The development of microbial resistance to antibiotics in treated animals, which can then be spread to people, is an important concern regarding the widespread use of antimicrobial feed additives in food production. There is circumstantial evidence that use of subtherapeutic doses of antimicrobials creates selective pressure for the emergence of antimicrobial resistance, which may be transmitted to the consumer from food or through contact with treated animals or animal manure. A ban on the use of antibiotics as feed additives decreased drug-resistant bacteria in a Danish study. Although overall mortality rates of chickens were not affected, more feed was consumed per kg of weight. Therapeutic use of antibiotics was increased, but the total volume of antibiotic use was significantly decreased. The EU has banned bacitracin, carbadox, olaquinox, tylosin, virginiamycin, avilamycin, flavophospholipol, lasalocid sodium, monensin sodium, and salinomycin as of 2009. There has been no reported evidence of any reduction in antimicrobial resistance in human bacterial pathogens as a result of the EU ban. This is understandable given that the most important and concerning cases of antimicrobial resistance in human medicine, namely methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococcus (VRE), *Streptococcus pneumoniae*, and others, are not food-borne pathogens, are not found in food or companion animals, and the drugs of interest are not used and were not used before the ban in livestock. The issue of antimicrobial resistance is critical for the immediate and long-term future of human medicine; however, the complexity of the issue and the difficulty with which it must be assessed ensure that clear answers are not imminent and the debate over the most appropriate path forward in the USA and abroad will continue.

PROBIOTICS

Probiotics promote the establishment and development of a desirable intestinal microbial balance. There is a delicate balance between normal and pathogenic microorganisms. This balance can be upset by poor husbandry conditions, disease, or stressors (eg, transport). Bacteria that

produce lactic acid can, in general, be beneficial to the animal; certain yeasts may also be beneficial. Their ability to increase growth and promote health are claimed to be due to one or more of the following factors: preventing colonization of the gut by pathogenic coliforms, altering GI absorption rate, and inhibiting bacterial growth and influencing the balance of bacteria in the gut. The probiotic feed additives consist of selected strains of lactobacilli and streptococci that alter the microbial species present in the GI system to the benefit of the treated animal. Unicellular yeasts are also used. The

production benefits are variable, and positive responses are more likely when a stressful management change may result in a change in balance of gut microflora. Thus, they are useful in some cases to minimize GI upsets or to help overcome stress due to weaning or transport. The unicellular yeast fungus may also have beneficial effects on rumen fermentation, thereby improving digestion and feed efficiency. The effect of probiotics in older animals may be reduced because of the well-established, balanced population of microflora that is less sensitive to minor detrimental husbandry challenges.

VACCINES AND IMMUNOTHERAPY

The adaptive immune system responds to microbial invasion by producing protective antibodies or cell-mediated immunity, or both. Appropriate administration of specific microbial antigens, as in a vaccine, can provoke effective, longterm resistance to infection. Conserved microbial molecules can also stimulate the development of innate immune responses. This too enhances resistance to infection and may be clinically useful.

ACTIVE IMMUNIZATION

Active immunization involves administration of vaccines containing antigenic molecules (or genes for these molecules) derived from infectious agents. As a result, vaccinated animals mount acquired immune responses and develop prolonged, strong immunity to those agents. When properly used, vaccines are highly effective in controlling infectious diseases. Several criteria determine whether a vaccine can or should be used. First, the actual cause of the disease must be determined. Although this appears self-evident, it has not always been followed in practice. For example, *Mannheimia haemolytica* can be isolated consistently from the lungs of cattle with respiratory disease; however, these bacteria are not the sole cause of this syndrome, and vaccines against the primary viral pathogens are required for full protection. In some important viral diseases (eg, equine infectious anemia, feline infectious peritonitis, and Aleutian disease in mink), antibodies may contribute to the disease process, and vaccination can therefore increase disease severity.

An ideal vaccine for active immunization should confer prolonged, strong immunity in vaccinated animals, as well as rapid onset of immunity. It should not cause adverse effects and should be inexpensive, thermo- and genetically stable, and, for production animals, adaptable to mass administration. It should preferably stimulate immune responses distinguishable from those due to natural infection, so that vaccination and eradication may proceed simultaneously. Vaccination is not always an innocuous procedure; adverse effects can and do occur. Therefore, all vaccination must be governed by the principle of informed consent. The risks of vaccination must not exceed those caused by the disease itself.

Vaccines may contain either living or killed organisms or purified antigens from these organisms. Vaccines containing living organisms tend to trigger the best protective responses. Killed organisms or purified antigens may be less immunogenic than living ones. Because they are unable to grow and spread in the host, they are less likely to optimally stimulate the immune system. Living viruses from vaccines, for example, infect host cells and grow. The infected cells then process the viral antigens, triggering a response dominated by cytotoxic T cells, a Th1 response (see p 814). Killed organisms and purified antigens, in contrast, commonly stimulate responses dominated by antibodies, a Th2 response. This antibody response may not generate optimal protection against some organisms. As a result, vaccines that contain killed organisms or purified antigens usually require the use of adjuvants to maximize their effectiveness. Adjuvants may,

however, cause local inflammation, and multiple doses or high doses of antigen increase the risks of producing hypersensitivity reactions.

Killed vaccines should resemble the living organisms as closely as possible. Chemical inactivation should cause minimal change to their antigens. Compounds used in this way include formaldehyde, ethylene oxide, ethyleneimine, acetyleneimine, and β -propiolactone.

Adjuvants

To maximize the effectiveness of vaccines, especially those containing poorly antigenic components or highly purified antigens, adjuvants are usually added. Adjuvants enhance response to vaccines and/or balance/shift the Th1/Th2 immune response. They can reduce the amount of antigen to be injected or the numbers of doses administered, and they may promote prolonged immunologic memory. It is believed that adjuvants work through three major mechanisms.

Depot adjuvants protect antigens from degradation and prolong immune responses as a result of the sustained release of antigen. Examples of depot-forming adjuvants include aluminum salts, such as aluminum hydroxide, aluminum phosphate, and aluminum potassium sulfate (alum), as well as calcium phosphate. These alum-based adjuvants also serve as very potent stimulators of toll-like receptors.

A second class of adjuvants consists of particles that effectively deliver antigen to antigen-presenting cells and so enhance antigen presentation. The immune system traps and processes particles such as bacteria or other microorganisms much more efficiently than soluble antigens. As a result, particulate antigens are much more effective than soluble ones. Examples of such adjuvants include emulsions, microparticles, immune-stimulating complexes (ISCOMs), and liposomes.

Immunostimulatory adjuvants consist of molecules that enhance cytokine production and so selectively stimulate helper cell responses. Many contain microbial products that often represent pathogen-associated molecular patterns. As a result, they activate dendritic cells and macrophages through toll-like receptors and stimulate the secretion of critical cytokines such as IL-1 and IL-12. These cytokines in turn promote helper T-cell responses and drive and focus the adaptive immune responses. Depending on the specific microbial product used, they may enhance either Th1 or Th2 responses. Commonly used microbial immunostimu-

lants include lipopolysaccharides (or their derivatives); killed anaerobic corynebacteria, especially *Propionibacterium acnes* and *Bordetella pertussis*; and saponins (triterpene glycosides) derived from the bark of the soapbark tree (*Quillaja saponaria*). Saponin-based adjuvants may selectively stimulate Th1 activity.

Adjuvants can be combined. For example, very effective adjuvants can be constructed by combining particulate or depot adjuvants with an immunostimulatory agent.

Types of Vaccines

Subunit Vaccines: Although vaccines containing whole killed organisms are economical to produce, they contain many antigens that do not contribute to protective immunity. They may also contain toxic components. Thus, it may be advantageous to identify, isolate, and purify the critical protective antigens. These can then be used in a vaccine by themselves. Thus, purified tetanus toxin, inactivated by treatment with formalin (tetanus toxoid), is used for active immunization against tetanus. Likewise, the attachment pili of enteropathogenic *Escherichia coli* can be purified and incorporated into vaccines. The antipilus antibodies protect animals by preventing bacterial attachment to the intestinal wall.

Antigens Generated by Gene

Cloning: The cost of physically purifying a specific antigen may be prohibitive. In such cases, it may be appropriate to clone the genes coding for protective antigens. The DNA encoding the desired antigens may be inserted into a bacterium or yeast, which then expresses the protective antigen. The recombinant organism is propagated, and the antigens encoded by the inserted genes are harvested, purified, and administered as a vaccine. An example of such a vaccine is one directed against the cloned subunit of *E. coli* enterotoxin. The cloned subunits are antigenic and function as effective toxoids. A purified subunit protein vaccine, called OspA, encoded by a gene from *Borrelia burgdorferi* effectively protects dogs against Lyme disease.

It is possible to clone viral antigen genes in plants. This has been successfully achieved for viruses such as transmissible gastroenteritis and Newcastle disease. The plants used include tobacco, potato, and corn. These plants contain very high concentrations of antigen, and successful vaccination may result from feeding the plants to animals.

Some recombinant vaccines contain viral structural proteins assembled into virus-like particles (VLPs). One or more viral proteins may be present in the VLP, and the particles may be either nonenveloped or enveloped. VLPs present viral antigen in a particulate form, and these antigens more closely resemble those of the infectious virus. VLPs are potent immunogens and may not require adjuvants. Because VLPs contain no viral genetic material, they cannot replicate in the vaccinee. The effectiveness of VLPs for animal vaccination has been shown in many experimental systems, but no veterinary VLP-based vaccines are commercially available at this time.

Attenuated Vaccines: The use of live organisms in vaccines presents many advantages. Most especially, they are usually more effective than inactivated vaccines in triggering cell-mediated immune responses. Their use, however, also presents certain hazards. Thus, the virulence of a live organism used for vaccination must be attenuated, so that it is able to replicate but is no longer pathogenic. The level of attenuation is critical to vaccine success. Underattenuation will result in residual virulence and disease (reversion to virulence); overattenuation will result in an ineffective vaccine. Rigorous reversion to virulence studies must be performed to demonstrate stability of the attenuation. Attenuated vaccines should not be used to vaccinate species for which they have neither been tested nor approved. Pathogens attenuated for one animal may be over- or under-attenuated in other animals. Thus, they may either cause disease or fail to provide adequate protection.

Attenuation has historically involved adapting organisms to growth in unusual conditions. Bacteria were attenuated by culture under abnormal conditions, and viruses were attenuated by growth in species to which they are not naturally adapted. Vaccine viruses may also be attenuated by growth in alternative media, such as tissue culture or eggs. This has been done for canine distemper, bluetongue, and rabies vaccines. Prolonged tissue culture was, for many years, the most usual method of attenuation.

For some diseases, related organisms normally adapted to another species may impart limited immunity. Examples include measles virus, which can protect dogs against distemper, and bovine viral diarrhea virus, which can protect pigs against classical swine fever.

Under rare circumstances, virulent organisms may be used for vaccination, eg, vaccination against contagious ecthyma (orf) of sheep. Lambs are vaccinated by rubbing dried, infected scab material into scratches made on the inner thigh, which produces local infection with only limited effects on the lambs; they become solidly immune. Because vaccinated animals may spread the disease, however, they must be separated from unvaccinated stock for a few weeks.

Considerable care must also be exercised in the preparation, storage, and handling of modified-live vaccines to avoid temperature extremes that can reduce viability of the organisms.

Gene-deleted Vaccines: Attenuation of viruses by prolonged tissue culture can be considered a primitive form of genetic engineering. Ideally, this resulted in the development of a strain of virus that was unable to cause disease. This was often difficult to achieve, and reversion to virulence was a constant hazard. Molecular genetic techniques now make it possible to modify the genes of an organism so that it becomes irreversibly attenuated. Deliberate deletion of the genes that code for proteins associated with virulence is an increasingly attractive procedure. For example, gene-deleted vaccines were first used against the pseudorabies herpesvirus in swine. In this case, the thymidine kinase gene was removed from the virus. Herpesvirus requires thymidine kinase to return from latency. Viruses from which this gene has been removed can infect neurons but cannot replicate and cause disease.

Similar genetic manipulation can be used to restrict the ability of bacteria to grow in vivo. For example, a modified-live vaccine is available that contains streptomycin-dependent *Mannheimia haemolytica* and *Pasteurella multocida*. These mutants depend on the presence of streptomycin for growth. When used in a vaccine, the absence of streptomycin will eventually result in the death of the bacteria, but not before a protective immune response has been stimulated.

Additionally, it is possible to alter the expression of other antigens so that a vaccine will induce an antibody response distinguishable from that caused by wild strains. This allows for a way to distinguish infected from vaccinated animals (referred to as DIVA).

Virus-vectored Vaccines: Another method to produce a highly effective living

vaccine is to insert the genes that code for protection antigens into an avirulent "vector" organism. These vaccines are created by deleting genes from the vector and replacing them with genes coding for antigens from the pathogen. The recombinant vector is then administered as the vaccine, and the inserted genes express the antigens when body cells are infected by the vector virus. The vector may be attenuated so that it will not be shed from the vaccinee, or it may be host-restricted so that it will not replicate itself within the tissues of the vaccinee. Virus-vectored vaccines are well suited for use against organisms that are difficult or dangerous to grow in the laboratory.

The most widely used vaccine viral vectors are poxviruses such as fowlpox, canarypox, vaccinia, and herpesvirus. These viruses have a large genome that facilitates insertion of new genes. They also express relatively high levels of the recombinant antigen. In at least some cases, vectored vaccines appear able to induce immunity even when high levels of maternal antibody are present. Canarypox-vectored vaccines that incorporate genes obtained from canine distemper virus are now used to immunize dogs, and a similar vector containing the gene encoding rabies glycoprotein effectively protects dogs and cats against rabies.

An innovative example of a vectored vaccine involves the use of a yellow fever viral chimera to protect against West Nile virus. This technology uses the capsid and nonstructural genes of the attenuated yellow fever vaccine strain 17D to deliver the envelope genes of other flaviviruses such as West Nile virus. The resulting virus is a yellow fever/West Nile virus chimera that is much safer than either of the parent viruses. The margin of safety can be further increased by introducing targeted point mutations into the envelope genes.

Another example is a vaccine directed against Newcastle disease. The vector is fowlpox virus, into which Newcastle disease HA and F genes are incorporated. It has the benefit of conferring immunity against fowlpox as well.

Vectored vaccines are also commercially available for avian influenza, West Nile virus and influenza infection in horses, feline leukemia, and for vaccinating wildlife against rabies. These vaccines are stable and can work in the absence of an adjuvant, and like the gene-deleted vaccines, allow for DIVA. Some are adaptable to mass vaccination. Field data collected on these vaccines indicate strong immunity and limited adverse effects.

Polynucleotide (DNA) Vaccines:

Animals may also be immunized by injection of DNA encoding viral antigens. This DNA can be inserted into a bacterial plasmid, a piece of circular DNA that acts as a vector. When the genetically engineered plasmid is injected, it can be taken up by host cells. The DNA is then transcribed, and mRNAs are translated to produce vaccine protein. Transfected host cells thus express the vaccine protein in association with major histocompatibility complex class I molecules. This can lead to the development of not only neutralizing antibodies but also cytotoxic T cells.

This type of DNA vaccine is used successfully to protect horses against West Nile virus infection. This approach has been applied experimentally to produce vaccines against the viruses that cause avian influenza, lymphocytic choriomeningitis, canine and feline rabies, canine parvovirus, bovine viral diarrhea, feline immunodeficiency virus-related disorders, feline leukemia, pseudorabies, foot-and-mouth disease, bovine herpesvirus-1 related disease, and Newcastle disease, among others. Because they can produce a response similar to that induced by attenuated live vaccines, these polynucleotide vaccines are ideally suited for use against organisms that are difficult or dangerous to grow in the laboratory. Some DNA vaccines appear to be able to induce immunity even in the presence of very high titers of maternal antibody. Immunization with purified DNA in this way allows presentation of viral antigens in their native form, because they are synthesized in the same way as antigens during a viral infection.

Administration of Vaccines

Route of Administration: The most common method of vaccine administration is by SC or IM injection. This approach is excellent for relatively small numbers of animals and for diseases in which systemic immunity is important. In addition, the veterinarian can be sure that an animal has received the appropriate dose of vaccine. However, local immunity is sometimes more important than systemic immunity, and in these cases, it is more appropriate to administer the vaccine at the site of microbial invasion. For example, intranasal vaccines are effective in protecting cattle against infectious bovine rhinotracheitis, cats against feline rhinotracheitis and calicivirus infections, and poultry against infectious bronchitis and Newcastle

disease. Unfortunately, these techniques require handling each individual animal.

Aerosolization of vaccines enables them to be inhaled by all the animals in a herd, group, or flock—an obvious advantage when the unit is large. This method is commonly used in the poultry industry. Alternatively, a vaccine may be administered in feed or drinking water, eg, vaccination of poultry for Newcastle disease and avian encephalomyelitis. Fish and shrimp may be vaccinated by immersion in a solution of antigen, which is absorbed through their gills.

Combination Vaccines: Because of the complexity of many disease syndromes or to avoid giving animals multiple injections, it is common to use mixtures of organisms in single vaccines. For example, for bovine respiratory disease complex, combined vaccines are available for bovine respiratory syncytial virus, infectious bovine rhinotracheitis virus, bovine viral diarrhea virus, parainfluenza 3 virus, and *Mannheimia haemolytica*. Combination vaccines are also commonly used in dogs and cats.

When a mixture of different antigens is inoculated simultaneously, they may compete with one another. However, manufacturers have recognized this and modified vaccines accordingly. Vaccines should never be mixed indiscriminately, because one component may dominate and interfere with responses to the other components.

Some veterinarians and owners have expressed concern that the use of vaccine mixtures in this way may somehow “overwhelm” the immune system. This concern is unfounded. The immune system has evolved to respond to complex organisms and multiple simultaneous challenges. The simultaneous administration of multiple vaccines to an animal does not present difficulties to the immune system of normal, healthy animals.

Vaccination Schedules: Although it is not possible to devise precise schedules for each vaccine, certain principles are common to all methods of active immunization. Newborn animals are passively protected by maternal antibodies and, in general, cannot be vaccinated until maternal immunity has waned. If stimulation of immunity is deemed necessary at this stage, the mother may be vaccinated during late pregnancy, timing the doses so that peak antibody levels are reached at the time of colostrum formation. Neonatal animals with antibodies are protected

against disease caused by that specific pathogen while maternal antibodies are present. However, passive antibody titers decrease exponentially. These maternal antibodies may drop below protective levels while, at the same time, preventing successful immunization. Inactivated vaccines are not very effective in conferring protective immunity in the face of maternal antibodies. Modified-live vaccines, however, may induce a protective primary immune response and some immunologic memory. Because the precise time of loss of maternal immunity cannot be predicted, young animals must usually be vaccinated multiple times to ensure successful immunization.

The interval between vaccine doses depends on an animal's immunologic memory. The duration of this memory depends on multiple factors, such as the nature of the antigen, the use of live or dead organisms, adjuvants used, and the route of administration. Some vaccines may induce immunity that persists for an animal's lifetime. Other vaccines may require boosting only once every 2–3 yr. Even killed viral vaccines may protect some animals against disease for many years. Unfortunately, the minimal duration of immunity has rarely been reliably measured. Annual revaccination has been the traditional rule, because this approach is administratively simple and has the advantage of ensuring that an animal is regularly seen by a veterinarian. It is likely that this is more than sufficient for most viral vaccines.

Individual animal and vaccine variability make it difficult to estimate the duration of protective immunity. Within a group of animals, there may be a great difference between the shortest and longest duration of protection. Vaccines may differ significantly in their composition, and although all may induce immunity in the short term, it cannot be assumed that they confer equal longterm immunity. A significant difference likely exists between the minimal level of immunity required to protect most animals and the level of immunity required to ensure protection of all animals.

A veterinarian should always assess the relative risks and benefits to an animal when determining the frequency of revaccination. Owners should be made aware that protection can be maintained reliably only when vaccines are used in accordance with the protocol approved by vaccine licensing authorities. The duration of immunity claimed by a vaccine manufacturer is the minimal duration supported by the data available at the time of approval.

It is common practice to rate vaccines according to their importance. Essential (or core) vaccines should be given to all animals of a species, and veterinarians should ensure that immunity is maintained throughout an animal's life by appropriate revaccination. Optional (or noncore) vaccines protect animals against sporadic, mild, or uncommon diseases and should be used only when circumstances warrant and when the benefits clearly outweigh the risks involved. For example, essential vaccines in dogs in the USA would normally include canine distemper, parvovirus, adenovirus, and rabies. Optional vaccines may include canine coronavirus, parainfluenza, *Bordetella*, leptospirosis, and Lyme disease.

Prime-boost Strategies: It has long been normal practice to use exactly the same vaccine for boosting an immune response as was used when first priming an animal. However, there is no reason why different forms of a vaccine should not be used for priming and for boosting. This approach is known as a prime-boost strategy. Under some circumstances, this may result in significantly improved vaccine effectiveness. Prime-boosting has been most widely investigated in attempts to improve the effectiveness of DNA vaccines. Combinations usually involve priming with a DNA vaccine and boosting with either a recombinant vaccine or with recombinant protein antigens.

Vaccine Failure

There are many reasons why vaccination may fail. In some cases, the vaccine may not be effective because it contains strains of organisms or antigens that are different from the disease-producing agent. In other cases, the method of manufacture may have destroyed the protective epitopes, or there may simply be insufficient antigen. Such problems are uncommon and can be avoided by using vaccines from reputable manufacturers. More commonly, an effective vaccine may fail because of unsatisfactory administration or storage. For example, a live bacterial vaccine may lose potency as a result of use of antibiotics. Route of administration may also affect efficacy. When vaccine is administered to poultry or mink by aerosol or in drinking water, the aerosol may not be evenly distributed throughout a building, or some animals may not drink adequate amounts. Also, chlorinated water may inactivate vaccines. If an animal is incubating the disease before vaccination, the vaccine may

not be protective; vaccination against an already contracted disease is usually impossible.

The immune response, being a biologic process, never confers absolute protection nor is equal in all individuals of a vaccinated population. Because the response is influenced by many factors, the range in a random population tends to follow a normal distribution: the response will be average in most animals, excellent in a few, and poor in a few. An effective vaccine may not protect those with a poor response; it is difficult to protect 100% of a random population by vaccination. The size of this unresponsive population varies among vaccines, and its significance depends on the nature of the disease. For highly infectious diseases in which herd immunity is poor and infection is rapidly and efficiently transmitted (eg, foot-and-mouth disease), the presence of unprotected animals can permit the spread of disease and disrupt control programs. Problems also can arise if the unprotected animals are individually important, as in the case of companion animals or breeding stock. In contrast, for diseases that are inefficiently spread (eg, rabies), 60%–70% protection in a population may be sufficient to effectively block disease transmission within that population and therefore may be satisfactory from a public health perspective.

The most important cause of vaccination failure in young animals is the inability of a vaccine to immunize in the presence of maternal antibodies. Vaccines may also fail when the immune response is severely suppressed, eg, in heavily parasitized or malnourished animals. (Such animals should not be vaccinated.) Stress, including pregnancy, extremes of cold and heat, and fatigue or malnourishment, may reduce a normal immune response, probably due to increased glucocorticoid production.

Adverse Reactions

Modern, commercially produced, licensed vaccines are very safe. Nevertheless, they are not always innocuous. The more common risks associated with vaccines include residual virulence and toxicity, which may cause injection-site reactions, depression, allergic responses, disease in immunodeficient hosts (modified-live vaccines), neurologic complications, and rarely, contamination with other live agents. For example, lesions of mucosal disease may be seen in calves vaccinated against bovine viral diarrhea. Vaccines that contain killed gram-negative organisms may also

contain bacterial cell-wall components that stimulate release of interleukin-1 and can cause fever and leukopenia and occasionally abortion. In general, it is prudent to avoid vaccinating pregnant animals unless the risks of not vaccinating are greater. Recent studies have indicated that vaccines are more likely to cause adverse effects in small dogs than in large. This is because both receive the same quantity of vaccine, and the smaller animals receive a relatively larger "dose." Certain modified-live virus bluetongue vaccines have been reported to cause congenital anomalies when given to pregnant ewes. The stress from a vaccination reaction may be sufficient to activate latent infections. For example, activation of equine herpesvirus has been demonstrated after vaccination against African horse sickness. Another adverse reaction is the "sting" that occurs when some vaccines are administered. This can cause problems for the vaccinator if the vaccinated animal objects strenuously. Some vaccines and vaccine mixtures may cause mild, transient immunosuppression.

In addition to potential toxicity, vaccines, like any antigen, may provoke hypersensitivity. For example, rapid allergic reactions (type I hypersensitivity) may occur in response to any of the antigens found in vaccines, including those from eggs or tissue-culture cells. All forms of hypersensitivity are more commonly associated with multiple injections of antigen; therefore, they tend to be associated with use of inactivated products. Immune complex (type III) reactions are also potential hazards of vaccination. These may cause an intense local inflammatory reaction or a generalized vascular disturbance such as purpura. An example of a type III reaction is clouding of the cornea in dogs vaccinated against canine adenovirus 1. Delayed (type IV) hypersensitivity reactions, expressed as granuloma formation, may develop at the site of inoculation in response to the use of depot adjuvants. Some chronic inflammatory reactions to long-acting feline vaccines may eventually lead to development of a fibrosarcoma at the injection site in cats.

Production of Vaccines

In most countries, government authorities regulate the production of biologics. In general, regulatory authorities license establishments that produce vaccines and inspect those premises to ensure that the facilities and the methods used are satisfactory. All vaccines are checked for safety, purity, potency, and efficacy. Safety

tests include confirmation of the identity of the organism used, freedom of the vaccine from contamination with extraneous organisms, and host and non-host safety toxicity tests. Because the living organisms found in vaccines normally die over time, it is necessary to ensure that they will be effective even after storage (stability). Although properly stored vaccines may still be efficacious after the expiration of their designated shelf life, this should never be assumed; expired vaccines should not be used.

PASSIVE IMMUNIZATION

Passive immunization involves the production of antibodies in one animal by active immunization. These antibodies can be stored (as immunoglobulins) and then administered to susceptible animals to confer immediate but short-lived protection. The transfer of maternal antibody to offspring via the placenta or colostrum is the natural (and very important) form of passive immunization. Immunoglobulins may be produced in cattle against anthrax, in dogs against distemper, and in cats against panleukopenia. Their most important role is in protection against toxigenic organisms, eg, *Clostridium tetani* or *C perfringens*. These immunoglobulins are generally produced in young horses by a series of immunizing inoculations.

To check the potency of preparations of immunoglobulin, comparison is made with an international biological standard and expressed in international units (IUs). Tetanus immunoglobulin is given to animals to confer immediate protection against tetanus. At least 1,500–3,000 IUs of immunoglobulin should be given to horses and cattle; at least 500 IUs to calves, sheep, goats, and pigs; and at least 250 IUs to dogs. The exact amount varies with the amount of tissue damage, degree of wound contamination, and time elapsed since injury. Tetanus immunoglobulin is of little use once clinical signs appear, although massive doses of up to 300,000 IUs may help.

Monoclonal Antibodies: In a normal immune response, antibodies are produced by many different plasma cell populations and are thus said to be polyclonal. Although these antibodies all combine with a specific antigen, they are a heterogeneous mixture of proteins. Homogeneous antibodies can be generated through the use of cloned cell lines called hybridomas; these monoclonal antibodies represent an alternative source

of passive immunization. Currently, however, these are mainly made by mouse hybridomas (and thus consist of mouse antibodies) and may sensitize other animal species.

Monoclonal antibodies are commonly used in diagnostic tests. Because they are homogeneous and specific, these antibodies can differentiate between closely related infectious agents in a manner impossible with conventional antibodies. For example, they can differentiate between the rabies viruses obtained from skunks, bats, or dogs.

NONSPECIFIC IMMUNOTHERAPY

Under some circumstances, it may be desirable to enhance the activity of an animal's immune system. This may include stimulation of the normal immune response to enhance protection and treatment of immunosuppressive conditions. Several types of immunostimulators have been used in veterinary medicine. They commonly contain microbial components, and many act by stimulating one or more toll-like receptors or related receptor systems.

BLOODBORNE ORGANISMS

Avian blood may contain various disease agents, including viruses, bacteria, rickettsiae, protozoa, microfilariae, and rarely fungi. These organisms can be identified by microscopic examination of wet mounts, buffy coat, or blood smears or by appropriate culturing and molecular techniques. Microscopically, some are within blood cells (*Plasmodium*, *Haemoproteus*, *Leucocytozoon*, *Isospora* [*Atoxoplasma*], *Hepatozoon*, *Babesia*, *Aegyptianella*), while others are free in the plasma (*Trypanosoma*, microfilariae, bacteria, spirochetes). None live exclusively in the blood; most are found in tissues but are present in blood during part of their life cycle. Some, such as microfilariae and *Plasmodium*, may have a periodicity when numbers or stages of parasites vary with time. In such cases, examining multiple smears at intervals will increase the likelihood of obtaining a diagnosis. Seasonal variations in infection rates relate to the activity of arthropod vectors. When possible, tissue cytology is also a useful adjunct to examination of blood. Most bloodborne organisms are either uncommonly or not associated with clinical disease. However, weakened or injured birds infected with hemoprotezoa may have higher mortality and slower recovery than uninfected birds. Examination for bloodborne organisms should be included in the clinical and diagnostic procedures for any ill bird.

Thin blood smears should be made with blood directly from the bird, if possible. Anticoagulants, storage, and cooling of the blood can distort protozoal morphology and introduce artifacts. A small drop of blood can be collected using a syringe and needle. The drop should be spread on a clean glass slide to make a thin smear. A Romanowsky-type stain that gives good polychromatic coloration (eg, Giemsa stain) should be used. At least 200 oil-immersion fields (~20,000 RBC) for single smears or 100 for multiple smears from the same bird should be examined. *Leucocytozoon* and microfilariae are found around the periphery of smears and can be easily seen on low-power magnification.

Bloodborne organisms in plasma or WBCs are concentrated in the buffy coat. The microhematocrit tube is cut just below the buffy coat above the packed RBCs. The

buffy coat should be expressed from the cut end with a small amount of plasma to make a suspension, and a thin smear prepared. Stained buffy coat smears are recommended to detect bacteria, spirochetes, and chronic *Leucocytozoon*, *Trypanosoma*, or *Isospora* (*Atoxoplasma*) infections. An excellent technique to identify low numbers of motile organisms such as spirochetes and microfilariae is direct examination of the buffy coat by darkfield or phase contrast microscopy. The buffy coat and all of the plasma should be expressed onto a glass slide and covered with a coverglass, which is depressed slightly to spread the buffy coat. The buffy coat/plasma interface should be examined with darkfield or reduced light microscopy to detect motile organisms.

To make a diagnosis of infection with an intracellular blood protozoan on a thin blood film, it first should be determined that the "parasites" in question are neither normal structure nor artifact. The following should then be determined: the host cell and whether it is normal or deformed beyond identification, whether pigment granules (hemozoin) are present or absent, and whether merogony is occurring (see TABLE 1). Identification of an organism beyond genus is difficult and usually unnecessary for clinical purposes.

Serologic and molecular diagnostic methods have been developed for avian hemoparasites but are usually not available commercially. Molecular methods are very sensitive and can detect infection when parasite numbers are too low to be detected in blood or tissue smears or by histology. Hemoparasites can also be studied by subinoculation of infectious blood in birds of the same or a known susceptible avian species. Bacteria can usually be identified by blood culture and molecular methods.

AEGYPTIANELLOSIS

Aegyptianellosis is an acute, tickborne, febrile disease caused by *Aegyptianella* spp, arickettsia in the family Anaplasmataceae. Infection of avian species, including chickens, turkeys, guinea fowl, quail, pigeons, crows, waterfowl, ratites, falcons, passerines, and psittacines has been described. A *pullorum* is pathogenic in chickens. Ticks, especially *Argas* spp,

TABLE 1 CHARACTERISTICS OF PROTOZOA ENCOUNTERED IN AVIAN BLOOD

Protozoan	Host Cell	Pigment Present	Merogony in Blood
<i>Plasmodium</i>	RBC	Yes	Yes
<i>Haemoproteus</i>	RBC	Yes	No
<i>Leucocytozoon</i>	RBC or WBC; distorted and enlarged often beyond recognition	No	No
<i>Isospora</i> (<i>Atoxoplasma</i>)	WBC; in nuclear indentation	No	No ^a
<i>Hepatozoon</i> ^b	WBC, large, elongated oval shape	No	No
<i>Babesia</i> ^b	RBC	No	No ^c

^a Multiple intracellular parasites may be seen in acute infections.

^b Uncommon to rare.

^c *Babesia* are pyriform and may be in a V, X, or fan pattern.

transmit the organism; infection can also be reproduced by blood inoculation. Organisms stain purple with Romanosky stain and appear as single or multiple, round, "signet-ring" (0.3–4 μ m) or irregular oval bodies in RBCs often lateral to the nucleus. They must be differentiated from trophozoites of *Plasmodium* and gametocytes of *Haemoproteus*. Infections are most common in tropical and subtropical areas of Africa, Asia, and Europe; infection of wild turkeys in Texas has been reported.

In endemic areas, infection is mild or asymptomatic. Ruffled feathers, anorexia, droopiness, diarrhea, fever, and high mortality in younger birds can occur in introduced or otherwise susceptible birds. Anemia, which can lead to right-side heart failure and ascites, enlargement of the liver and spleen, enlarged discolored kidneys, and pinpoint serosal hemorrhages, can be seen. Infestation with larval argasid ticks and *Borrelia* infection (see p 2813) may accompany the disease.

Tetracyclines, especially doxycycline, effectively control the disease and possibly eliminate the organism from chronically infected birds. Tick control is an important adjunct to treatment.

ISOSPORIASIS

(Atoxoplasmosis, Lankesterellosis)

The taxonomic position of the Eimeriidae coccidia genera *Atoxoplasma* and *Isospora* has been subject to debate. It is currently suggested that *Atoxoplasma* be considered

synonymous with *Isospora* and unified in a single group of coccidia with intra and extra-intestinal forms.

Isosporiasis is a disease of passerine birds. Canaries, finches, sparrows, and species of the Sturnidae family (starlings, mynahs) are most often affected. Very rare cases of infection have also been reported in raptors. Poultry are not known to be affected.

Isospora has a direct life cycle that includes an intestinal and an extra-intestinal, systemic phase. Schizogony occurs in the intestinal epithelial cells as well as the circulating mononuclear cells. Gametogony and oocyst formation occur in the intestinal epithelial cells, and oocysts are passed in the feces. Transmission is fecal-oral.

Infection is most often not pathogenic, and high parasitemia may be seen in young birds. In susceptible species or weakened birds, mortality can be high (as much as 80%) and rapid, especially in fledglings. *Isospora* infection complicates management and is a threat to successful captive breeding of some species such as the endangered Bali mynahs. Clinical signs include listlessness, diarrhea, anorexia, and weight loss. In acutely affected birds, there is marked hepatomegaly and splenomegaly, often with multifocal necrosis. The enlarged liver and gallbladder can be seen through the abdominal wall, especially if it is moistened with alcohol, which provides the basis for the common name of black spot disease in passerine birds. Parasite-infected mononuclear cells are present in blood and organ impression smears or aspirates,

especially in the liver and spleen. Oocysts are present in droppings. *Isospora* are pale-staining, nonpigmented, oval, intracytoplasmic bodies within mononuclear cells thought to be lymphocytes. Usually, cells contain a single parasite, but multiple organisms can be seen in severe, acute infections. Presence of the protozoan causes the nucleus to curve around it, giving the appearance that the organism is located within an indentation of the nucleus.

Diagnosis is difficult in chronically infected older birds. Very few parasites are present in blood and tissues, and oocysts are shed intermittently, sometimes in high numbers. A PCR test is available and can be performed on blood, tissues, or feces, although its sensitivity is poor in fecal samples. PCR is useful to determine the incidence and prevalence in a collection, confirming the diagnosis, and possibly evaluating the efficacy of treatment. PCR cannot be used to ascertain that a bird is free of *Isospora*, however. Buffy coat and organ smears are other but less sensitive diagnostic methods. Negative findings should not be interpreted to mean that infection is not present. In some chronically infected birds, hepatic and splenic enlargement persists because of infiltrations with high numbers of large lymphoid cells that serve as host cells for the parasite. Histopathologically, organisms are difficult to find and identify, and lesions may be mistaken for those of lymphoma.

Toltrazuril, sulfachlorpyridazine, and sulfachlorpyrazine have successfully reduced mortality and oocyst shedding. It is unlikely that these drugs clear the organism from the bird. Good management procedures, including isolation of age groups and scrupulous cleanliness (particularly daily cleaning before oocysts sporulate) help control the disease. Disinfectants have little effect on oocysts.

FILARIASIS

Microfilariae are commonly found in the blood of some wild bird species but are rare to absent in poultry except in southeast Asia where infections in chickens and waterfowl occur. Prevalence of microfilariae in wild birds varies from 3% to 6% but can be as high as 20% in some species such as ptarmigan, swans, and geese. When psittaciformes were commonly imported, it was not unusual to observe microfilariae in their peripheral blood, especially in imported cockatoos.

At least 16 genera of filarids are found in avian species. All have an indirect life cycle,

with bloodsucking insects (eg, lice, mosquitoes, midges) serving as intermediate hosts. Adults mature in body cavities, including the eye and ventricles of the brain, respiratory system, cardiovascular system, or connective tissues; some produce characteristic subcutaneous nodules. Microfilariae may be numerous in circulation, especially in the skin vasculature. Microfilariae can be seen in blood smears. However, a buffy coat smear obtained from a microhematocrit tube is a more sensitive method of diagnosis. Increased numbers of microfilariae have been seen in stressed individuals, but they rarely cause clinical disease or mortality. A possible exception is infection of emus with *Chandlerella quiscali*, a common filarid of the brain of free-living grackles. Affected emus show signs of CNS disease (eg, torticollis, ataxia). *C quiscali* apparently does not produce microfilariae in emus. Treatment with ivermectin, fenbendazole, or levamisole, and surgical removal of adult parasites, have been used.

HAEMOPROTEUS INFECTION

Haemoproteus spp is the most common blood parasite in birds, especially nondomestic birds. More than 120 species have been reported. *Haemoproteus* spp are found in free-living ducks, quail, and turkeys but are rare to absent in commercial flocks, probably because of limited vector exposure or very specific feeding habits of *Culicoides* spp and hippoboscids flies, the invertebrate vectors. *Haemoproteus* is considered nonpathogenic in most avian species. Birds are usually asymptomatic; however, *Haemoproteus* infection may be more often significant than previously thought, based on increasing reports documenting decreased host fitness, nestling mortalities, fledging success, and delayed recovery in infected birds versus uninfected birds. Anemia, anorexia, weight loss, and depression have been reported. Rarely fatal disease occurs. Clinical disease is usually attributed to anemia, presence of megaloschizonts in the musculature, or host-cell destruction.

In poultry, infection with *H. lophortyx* in bobwhite quail caused clinical disease and increased mortality with as much as 20% flock loss. Quail 5–10 wk old were usually affected, and clinical signs included reluctance to move, prostration, and death. Gross lesions included congested spleen and liver and hemorrhagic streaks in the muscles. Histology revealed myositis with

megaloschizonts in the musculature, especially of the legs and back, and hemosiderin accumulation in the splenic macrophages. Experimental infection in turkeys with *H meleagridis* resulted in lameness, diarrhea, anorexia, and depression. Histologic lesions were associated mainly with megaloschizont development in the musculature. Infection in racing pigeons (called pigeon malaria) is commonly asymptomatic but often blamed for poor performances that are due to other diseases or inadequate housing and management. Clinical disease in Columbiformes is rare.

Diagnosis is made by examination of stained blood smears and observation of large, pigmented gametocytes in mature RBCs that partially or occasionally completely encircle the nucleus without displacing it. Merozoites are not seen in the peripheral blood. Schizogony within the endothelial cells of the lung, liver, and spleen may be seen histologically. PCR tests for *Haemoproteus* have been developed. Little is known about effective treatment. Antimalarial drugs reduce the parasitemia but do not eliminate the parasite. Chloroquine, primaquine, quinacrine, and buparvaquone have been used in pigeons. Combinations of chloroquine and primaquine or chloroquine and mefloquine have been used to treat owls. Treatment is not recommended in asymptomatic birds. Measures to control invertebrate vectors, such as screening of aviaries, help prevent transmission and heavy infections.

LEUCOCYTOZOONOSIS

Infections with *Leucocytozoon* spp are most often subclinical but can occasionally cause clinical and even fatal disease. Mortality varies greatly with the strain of parasite, species, degree of exposure, age, immune status, and other factors. Outbreaks of leucocytozoonosis have been reported in chickens (Asia, Africa), turkeys (North America), waterfowl (North America, Europe, Asia), and a number of free-living and captive avian species throughout the world. Species in domestic birds include *L simondi* in waterfowl; *L smithi* in turkeys; and *L caulleryi*, *L sabrazesi*, *L andrewsi*, and *L schoutedeni* in chickens. *L caulleryi* can be highly pathogenic, causing a lethal hemorrhagic disease of chickens in southeast Asia. *L simondi* causes mortality in ducks and geese. Numerous *Leucocytozoon* spp infect nondomestic birds. Clinical disease and mortality result from anemia caused by

antierthrocytic factors produced by the parasite, high numbers of the large gametocytes blocking pulmonary capillaries, or parasites invading the endothelium of vessels in tissues (brain, heart, etc) where they form megaloschizonts that occlude vessels and result in multifocal necrosis.

Parasitemia often increases dramatically in late April and early May (called spring rise), just before arthropod vectors, black flies (*Simulium* spp), or biting midges (*Culicoides* spp) increase. Ducks that have recovered from infection with *L simondi* may relapse when light cycles are manipulated to increase egg production. Increased levels of prolactin have been suggested as a possible cause.

Acute disease is seen more often in the young with high parasitemia and when black flies or biting midges are most abundant. Subacute or chronic disease is seen in the young outside fly season and in older birds at any season; parasitemia is usually low. Recovered birds remain carriers and serve as a reservoir for young, susceptible birds.

Clinical Findings, Lesions, and

Diagnosis: Ducklings or turkey poults are listless and show various combinations of the following signs: anemia, leukocytosis, tachypnea, anorexia, diarrhea with green droppings, and CNS signs. Mortality in ducklings can reach 70%. Mortality is low in adult ducks or turkeys. Egg production and hatchability is decreased. Signs are evident ~1 wk after infection and coincide with the onset of parasitemia. Visibly affected birds die after 7–20 days or may recover with sequelae of poor growth and egg production. Hemorrhages, splenomegaly, and hepatomegaly are seen. Grossly visible white dots in affected organs are megaloschizonts. Histologic lesions are associated with megaloschizont development in the spleen, liver, heart, and other organs. Infection with *L caulleryi* in chickens has a tropism for the

Leucocytozoon parasite in the peripheral blood of a turkey. Courtesy of Dr. Jean Sander.

reproductive tract and is associated with oviduct inflammation and edema and decreased egg production. Peritoneal, perirenal, and subdural hemorrhages are reported with severe disease.

In blood smears, gametocytes may be seen, especially along the edges and tail of the smear. *Leucocytozoon* is identified by large gametocytes that lack pigment and distort the host cell (RBC or WBC), making it no longer identifiable. The shape of gametocytes varies: some are elongated with long tapering extremities, whereas others are round. Serology may detect prior infection. PCR tests have been developed for diagnosis of leukocytozoonosis.

Treatment and Control: Treatment usually is not effective. Preventive medication using pyrimethamine (1 ppm) and sulfadimethoxine (10 ppm) combined in the feed controls *L. caulleryi*. Clopidol (0.0125%–0.025%) controls *L. smithi*. Measures to control invertebrate vectors are helpful. Humoral immunity resulting from vaccination will protect against *L. caulleryi* infection. Treatments with quinacrine hydrochloride or trimethoprim/sulfamethoxazole solution have been used in raptors; parasitemia is reduced, but the infection is not cleared.

PLASMODIUM INFECTION

Plasmodium spp infect a wide variety of domestic and wild birds in most areas of the world. Infection is often not species specific. Thirty-five species of *Plasmodium* are considered valid species. *P. gallinaceum*, *P. juxtanucleare*, and *P. durae* are the most pathogenic species found in poultry. *P. gallinaceum* infects chickens in Asia and Africa and causes low mortality in indigenous chickens; however, rates may be as high as 80%–90% in commercial birds. *P. juxtanucleare* infects chickens and turkeys in Asia, Africa, and South America; most infections are mild or asymptomatic. *P. durae* infects turkeys and gallinaceous birds other than chickens in Africa; mortality in turkeys can approach 100%. *P. hermani* infects turkeys and bobwhite quail. Clinical malaria has not been reported from poultry in North America, but indigenous wild turkeys can become infected with at least four different *Plasmodium* species. The most common species affecting wild birds is *P. relictum*, which has been found in at least 360 species of birds. Asymptomatic infections in endemic or introduced birds can be spread via mosquitoes and cause fatal disease in introduced (eg, zoo birds) or

resident (eg, Hawaiian avifauna) birds, respectively. Passerine birds commonly carry the organism asymptotically. Cold-climate species held outside their natural range are particularly susceptible to develop clinical disease (eg, penguins, snow owls, and gyrfalcons in captivity). Invertebrate hosts are ornithophilic mosquitoes, usually *Culex*, *Culiseta*, or *Aedes* spp.

Clinical Findings, Lesions, and

Dagnosis: Infection with *Plasmodium* spp may be nonclinical or cause illness characterized by weakness, lassitude, dyspnea, anemia, abdominal distention, increased right heart weight, ocular hemorrhage, biliverdinuria, and death. Death results from severe anemia or blockage of capillaries in the brain, lung, or other vital organs by exoerythrocytic meronts in endothelial cells. The liver and spleen are markedly enlarged and often discolored (dark brown to black). Pigmented parasites including meronts are found in both immature and mature RBCs. Infrequently, parasites are found in thrombocytes and WBCs. In birds that die acutely, organisms may be sparse or absent in blood, but numerous meronts can be found in capillaries by histology or examination of squash or impression smears of brain, lung, liver, and spleen. Serologic and molecular diagnostic methods exist but are not available commercially. Serology and PCR can detect infection when parasites are too few to be identified in blood smears.

Treatment and Control: Therapy is variably effective in treating infected birds or flocks. Persistent parasitemia or relapse may occur during and after treatment. Birds that survive initial infections may be refractory to subsequent infections. Prevention of exposure to mosquitoes by appropriate housing is essential.

No antimalarial drug is commercially available or approved to treat poultry flocks. However, a mixture of trimethoprim and sulfaquinoxaline in the feed for a 5-day period has been shown to be efficacious against experimentally induced *P. gallinaceum* malaria in chickens. An experimental study on the pathogenicity and chemotherapy of *P. durae* suggested that a combination of sulfamonomethoxine and sulfachloropyrazine could be an effective therapy; halofuginone was suggested for chemoprophylaxis in endemic areas. Chloroquine administered by gavage at 50 mg/kg in Leghorn chickens experimentally infected with *P. juxtanucleare* may have reduced parasitemia.

In caged birds and penguins, chloroquine (10 mg/kg) and primaquine (0.3–1 mg/kg) is given orally and followed by administration of chloroquine (5 mg/kg) 6, 24, and 48 hr later. Chloroquine in drinking water (250 mg/120 mL) has also been used in songbirds. Grape or orange juice can disguise chloroquine's bitterness. Treatment including both primaquine and chloroquine is recommended over chloroquine alone, because only primaquine is active against the tissue schizonts. Chloroquine has activity against erythrocytic schizonts and gametocytes. Primaquine also has activity against erythrocytic gametocytes. When aliquoting the medications, note that a 500-mg tablet of chloroquine contains 300 mg of active base, and a 26-mg primaquine tablet contains 15 mg of active base.

In raptors, control of the disease has been achieved by oral administration of mefloquine (30 mg/kg) repeated 12, 24, and 48 hr after the initial dose. Alternatively, a combination of chloroquine (25 mg/kg) and primaquine (1.3 mg/kg) can be given orally and is followed by the administration of chloroquine (15 mg/kg) 12, 24, and 48 hr later. In endemic areas, mefloquine once a week (30 mg/kg) has been used successfully for chemoprophylaxis in large falcons.

In a DNA vaccine trial in captive African black-footed penguins, parasitemia and clinical disease were successfully reduced.

OTHER BLOODBORNE ORGANISMS

Trypanosomes have been described in several avian species but rarely if ever cause clinical disease. They are more commonly identified in organ smears, especially bone marrow, than in peripheral blood, and can be cultured. Invertebrate hosts are thought

to be any of several bloodsucking insects. Treatment is not warranted.

Borreliae are tickborne (*Argas* spp) spirochetes that can cause fatal systemic disease. Penicillins, tetracyclines, tylosin, and tick control are used for prevention and treatment. (See also AVIAN SPIROCHETOSIS, p 2813.)

Babesia spp are uncommon, nonpigmented, pyriform-shaped, erythrocytic protozoan parasites of birds. Natural infections of penguins, falcons, cranes, and several other avian species occur. Ticks are considered to be the invertebrate hosts. V, X, or fan shapes characterize dividing forms. Knowledge regarding their significance, treatment, or control in birds is limited. Only *B. shorti*, which rarely occurs in falconiformes, has been reported to be pathogenic. Reported treatment in infected falcons was IM administration of 2 or 3 doses of imidocarb dipropionate (5–13 mg/kg) 1 wk apart.

Hepatozoon is a protozoan parasite infrequently identified in birds. Prevalence in wild birds is 2%–5%. It produces relatively large, nonpigmented, elongated gametocytes with rounded ends that can be found in WBCs. Gametocytes are usually not located within an indentation of the nucleus, whereas *Isospora* is oval and partially encircled by the nucleus. The life cycle in birds is uncertain, but argasid ticks and fleas have been identified as probable vectors for *Hepatozoon* infecting swallows. *Ixodes* ticks, mites, and other arthropods may also be involved. *Hepatozoon* spp are not known to be pathogenic.

Zoites of other sporozoa (eg, *Toxoplasma*, *Sarcocystis*) and organisms normally in the digestive tract (eg, trichomonads, coccidia, histomonads) may be transiently found in blood. The latter often also produces liver lesions. (See also TRICHOMONOSIS, p 2804, and HISTOMONIASIS, p 2835.)

CHICKEN ANEMIA VIRUS INFECTION

(Chicken infectious anemia, Blue wing disease, Anemia dermatitis syndrome, Hemorrhagic aplastic anemia syndrome)

Etiology, Epidemiology, and Pathogenesis: Chicken anemia virus (CAV), a 25 nm, nonenveloped, icosahedral virus with a single-stranded, circular DNA genome, is the only member of the *Gyrovirus* genus of the Circoviridae family. The genome codes for three viral proteins (VP). VP1 is the

capsid protein, but VP2 may be needed as a scaffold protein to allow proper folding of VP1. VP2 has also a dual-specificity protein phosphatase (DSP) activity, and mutations affecting the DSP activity resulted in attenuation of virus replication in vivo. VP3, or apoptin, is a nonstructural protein that

induces apoptosis in infected cells. CAV infects only chickens, although antibodies have been detected in Japanese quail. The virus is present worldwide based on serology and virus isolation. The disease, chicken infectious anemia, has been described in most countries where chickens are raised commercially.

Horizontal transmission of CAV is by the fecal-oral route, perhaps by the respiratory route, and through infected feather follicle epithelium. Vertical transmission occurs when seronegative hens become infected and continues until neutralizing antibodies develop. Chicks hatched from these eggs are viremic, and CAV can rapidly spread horizontally from these chicks to susceptible, maternal antibody-negative hatchmates. Roosters shedding CAV in semen are another source of vertical transmission. Vaccination of seronegative flocks before the onset of egg production is recommended to prevent vertical transmission.

Maternal antibody-negative chicks are susceptible to infection and disease until 1–2 wk old. In contrast, maternal antibody-positive chicks are protected from disease and probably from infection. Age resistance to clinical disease, but not infection, begins at ~1 wk of age. The age resistance can be overcome by coinfection with viruses causing immunosuppression such as bursal disease virus (see p 2837), Marek's disease virus (see p 2849), and reticuloendotheliosis virus (see p 2854).

Many SPF flocks develop antibodies to CAV during or after onset of sexual development. Spread of infection by CAV-contaminated embryo- or cell-culture-derived vaccines is possible.

When day-old susceptible chicks are inoculated IM with CAV, viremia occurs within 24 hr. Virus can be recovered from most organs and rectal contents as long as 35 days after inoculation. The principal sites of CAV replication are hemocytoblasts in the bone marrow, precursor T cells in the cortex of the thymus, and dividing CD4 and CD8 cells in the spleen. Replication in the hemocytoblasts leads to anemia, while replication in the T cells causes immunosuppression. Neutralizing antibodies are detectable 21 days after infection, and clinical, hematologic, and pathologic parameters return to normal ~35 days after infection. CAV infection has adverse effects on proliferative responses of spleen lymphocytes and on the production of interleukin-2 and interferons by splenocytes. Infection can cause a marked decrease in generation of antigen-specific cytotoxic T cells and T-helper cells directed

against other pathogens. In addition to T-cell defects, macrophage functions such as Fc-receptor expression, phagocytosis, and antimicrobial activity may be impaired. Subclinical, horizontally acquired infection with CAV in broiler progeny of seropositive parent flocks may be associated with impaired economic performance.

Clinical Findings: Signs of illness or adverse effects on egg production do not occur when seronegative adult chickens become infected. However, vertical transmission or infection of maternal antibody-negative chicks before 1 wk of age can cause clinical disease 12–17 days after hatching or infection. Chicks are anorectic, lethargic, depressed, and pale. PCV is low (in chicks, anemia is defined as a PCV ≤ 27), and blood smears often reveal anemia, leukopenia, or pancytopenia depending on the state of the disease. Blood may be watery and clot slowly. Mortality rates are variable but may be high with secondary complicating infections.

Lesions: Organs are pale; the thymus is generally atrophied, and the bursa of Fabricius may be small. Bone marrow is pale or yellow. Hemorrhages may be present in or under the skin, muscle, and other organs. Histologically, lymphoid cell populations are depleted in primary and secondary lymphoid organs. Granulocytic and erythrocytic compartments in the bone marrow are atrophic or hypoplastic.

Diagnosis: A tentative diagnosis is based on history, signs, and gross and histopathologic lesions. Confirmation requires detection of virus or viral DNA in the thymus or bone marrow. PCR and quantitative PCR techniques are commonly used to demonstrate the presence of CAV. Viral isolation can be used but is slow and expensive. To isolate CAV, chloroform-treated extracts of tissues are inoculated in MDCC-MSB1 or MDCC-147 cultures (both are lymphoblastoid cell lines derived from Marek's disease tumors) or into susceptible, immunocompromised and maternal antibody-negative day-old chicks. Commercial ELISA kits are available to detect serum antibodies to CAV and can be used to identify breeder flocks that are seronegative before egg production and to monitor the efficacy of vaccination.

Treatment and Prevention: There is no specific treatment. Secondary bacterial infections may be treated with antibiotics. Live vaccines are available for vaccination

of antibody-negative breeder flocks before the start of egg production. Administration is by injection or by addition to the drinking water depending on the type of vaccine available in individual countries. A vaccine has been approved in the USA for use in broilers as young as 7 days old; administration is by addition to the drinking water. In some areas, transfer of litter to noncontaminated premises and the addition of crude

homogenates of tissues from affected chickens to the drinking water have been used to ensure infection and seroconversion of parent flocks before they begin to lay eggs, thereby diminishing the risk of egg transmission. However, these procedures are extremely risky and not acceptable. Because of the synergism between CAV and other immunosuppressive viruses, control of the latter is also important.

DISSECTING ANEURYSM IN TURKEYS

(Aortic rupture, Internal hemorrhage)

Dissecting aneurysm is a fatal disease of turkeys. It is characterized by sudden death of rapidly growing birds with massive internal hemorrhage. The hemorrhage results from rupture of aneurysms formed in various parts of the vascular system. The frequency with which the posterior aorta is affected has given rise to the term "aortic rupture." The disease has been reported in North America, Europe, and Israel. Most breeds of turkeys are susceptible, and the largest and most rapidly growing males, 8–24 wk old, are affected most often; females are also affected but at a lower incidence.

Etiology: The cause is unknown. Likely, several factors contribute to the development of fatal cases. For the disease to occur, turkeys must be fed and managed in such a way that they grow rapidly, and they must have a genetic susceptibility. A prolonged lipemia generally develops during the period of rapid growth, and the period of greatest mortality typically corresponds to a sharp rise in blood pressure, with dissecting aneurysms developing at the site of arteriosclerotic plaques. The lipemia may result from a high dietary intake of fat or from the effects of hormonal factors, such as high dietary concentrations of estrogens. Although β -aminopropionitrile, the toxic agent in *Lathyrus odoratus*, is capable of producing the disease, there is no evidence that this or other nitriles are responsible for dissecting aneurysms in turkeys under natural conditions. The enzyme lysyloxidase, isolated from turkey aortas and active on tropoelastin and collagen cross-linking, was found to be much lower in males than in females; this may be a factor in the development of spontaneous aortic aneurysms in male turkeys.

Clinical Findings: Affected turkeys that had shown no premonitory signs are found dead with marked pallor of the head and neck. Occasionally, a caretaker observes an apparently healthy turkey die within a few minutes. The incidence is usually <1% but may be as high as 10%. In the past, when male turkeys were implanted with stilbestrol, the incidence was as high as 20%.

Lesions: The carcass is markedly anemic, with large quantities of clotted blood in the peritoneal cavity and over the kidneys or in the pericardial sac. The rupture in the ventral wall of the posterior aorta at about the position of the testes, or in the cardiac atrium, can be located readily by carefully washing away the blood clot. The aortic lumen may contain an organized, adherent thrombus at the site of rupture. Ruptures in smaller blood vessels are more difficult to locate. Almost always, an intimal thickening or a large, fibrous plaque is present in the region of the rupture. The tunica intima and media are thrown into deep folds and separated from the tunica adventitia. Marked accumulation of lipids in the thickened intima and in the fibrous plaques can be identified by stains. Fibers of the tunica media may show degenerative changes and infiltration with heterophils and macrophages.

Diagnosis: The diagnosis is made by finding large clots of blood in the coelomic cavity (aortic rupture) or within the pericardial sac (auricular rupture) of rapidly growing male turkeys. Dissecting aneurysm should be differentiated from hypertensive angiopathy (see p 2789), which is also seen in rapidly growing turkeys. In hypertensive angiopathy, the major lesions include pulmonary edema and supracapsular perirenal hemorrhage.

Treatment, Control, and Prevention:

There is no known treatment. Coagulants and vitamin K are useless, because there is no defect in the clotting mechanism. Losses sometimes may be reduced during the critical period between 16 and 23 wk of age by limiting feed intake

or slowing growth rate by reducing the energy level of the diet. High-fat diets should not be fed during this period. Some studies have indicated that the incidence of aortic rupture can be reduced by adding copper at 125–250 ppm to the diet from at least 4 wk of age until market.

INCLUSION BODY HEPATITIS/ HYDROPERICARDIUM SYNDROME

(Hepatitis hydropericardium)

Adenoviruses are widespread throughout all avian species. Studies have demonstrated the presence of antibodies in healthy poultry, and viruses have been isolated from normal birds. Despite their widespread distribution, most adenoviruses cause no or only mild disease; however, some are associated with specific clinical conditions. Avian adenoviruses (AAVs) in chickens are the etiologic agents of two important diseases known as inclusion body hepatitis (IBH) and hydropericardium syndrome (HP). Although in some cases each disease is observed separately, the two conditions have been frequently observed as a single entity; therefore, the name hepatitis hydropericardium has been widely used to describe the pathologic condition. The syndrome is an acute disease of young chickens associated with anemia, hemorrhagic disorders, and hydropericardium. It is a common disease in several countries, where broilers are severely affected, resulting in high mortality rates.

Etiology, Transmission, and Pathogenesis:

The AAVs classified in the genus *Aviadenovirus* (formerly group I) are the etiologic agents of this condition. Although there are 12 different serotypes of AAV, the most common viruses isolated in cases of IBH/HP belong to serotypes 4 and 8. These AAVs are capable of producing the disease without the immunosuppressive effects of associated viruses such as infectious bursal disease (IBDV, see p 2837) or other immunosuppressive agents. However, the association with immunosuppressive viruses such as IBDV and chicken anemia virus (CAV, see p 2785) will result in a more severe disease.

Horizontal and vertical transmission play an important role in IBH/HP. Vertical

transmission has been described in progeny from breeder flocks infected with AAV serotypes 4 and 8. Horizontal transmission has also been demonstrated; young chicks in contact with infected chicks can die of peracute IBH/HP. Infection with some strains of AAVs may result in minimal hepatic disease; however, if birds have been infected with immunosuppressive viruses (IBDV, CAV, Marek's disease), the clinical disease becomes evident.

Clinical Findings, Lesions, and

Diagnosis: Sudden mortality usually is seen in chickens <6 wk old and as young as 4 days of age. Mortality normally ranges from 2%–40%, especially when birds are <3 wk old. However, in some outbreaks, mortality has reached 80%. Mortality rates also vary depending on the pathogenicity of the virus and infection with other viral or bacterial agents. Signs associated with diseases caused by other pathogens (eg, bacteria, fungi, or viruses) commonly occur if birds are immunosuppressed.

Hepatitis hydropericardium (right), normal liver on left. Courtesy of Dr. Pedro Villegas.

Flocks of 3- to 5-wk-old broilers with HP may not show specific clinical signs, but abrupt onset of mortality, lethargy, huddling with ruffled feathers, and yellow, mucoid droppings may be seen. The duration of the infection usually ranges from 9–14 days with morbidity of 10%–30% and a daily mortality of 3%–5%. Gross lesions include as much as 10 mL of a straw-colored transudate in the pericardial sac, generalized congestion, and an enlarged, pale, friable liver. Histopathologic lesions include myocardial edema in the heart with degeneration, necrosis, and mild mononuclear cell infiltration. Basophilic intranuclear inclusion bodies may be present in the liver. A tentative diagnosis is based on typical microscopic findings and confirmed by isolating adenoviruses from the liver. Serology, restriction enzyme analysis, and PCR are used to classify adenoviruses isolated from clinical cases. This information is used for epidemiologic studies.

Treatment and Prevention: As with many other viral diseases, there is no treatment. Antibiotics may help prevent secondary bacterial infections. Sulfonamides are contraindicated if evidence of hematologic disease or immunosuppression is seen.

Vaccines against IBH/HP are not commercially available in the USA; however, in other countries both live and inactivated vaccines are used to control the syndrome. The AAV serotypes most frequently used to prepare commercial vaccines are serotypes 4 and 8. Primary breeders with stringent biosecurity practices sometimes use autogenous inactivated vaccines to ensure the transfer of maternal immunity from breeding flocks to their progeny. In Australia, a live vaccine given via drinking water was developed for breeders between 10–14 wk of age. In other countries, including Mexico, Pakistan, and many countries in South America, inactivated vaccines are routinely used to vaccinate breeders and broilers. When breeders are properly vaccinated, antibodies generated by the vaccine are transmitted to the progeny, providing protection against field infections and clinical disease. Broilers are vaccinated at <10 days of age when their parents either do not have serotype-specific adenovirus antibodies or maternal antibody transmission is erratic because of improper vaccination procedures that result in a substantial number of unvaccinated birds.

PERIRENAL HEMORRHAGE SYNDROME OF TURKEYS

(Hypertensive angiopathy, Sudden death syndrome of turkeys)

Perirenal hemorrhage syndrome (PHS) is a noninfectious cardiovascular disorder usually affecting rapidly growing male turkeys 8–15 wk old. It is characterized by sudden death, perirenal hemorrhage, and hypertrophic cardiomyopathy. Mortality is usually 0.5%–2% but can be higher; there is no morbidity. Healthy, rapidly growing flocks are more likely to be affected.

The pathogenesis is unknown, but PHS is apparently unrelated to pulmonary function or hypertension. Inadequate or inappropriate cardiac response to exercise, resulting in systemic hypotension and vasodilation, ventricular arrhythmia, and sudden death, appears most likely. Acute congestive heart failure secondary to cardiac hypertrophy is also a potential cause. Renal hemorrhage may occur due to severe passive congestion; acute blood loss is likely not the primary cause of death because the extent of perirenal hemorrhage is variable and often mild.

Gross lesions include food in crop and stomach, enlarged dark red to purple spleen, variable retroperitoneal hemorrhage around one or both kidneys, generalized congestion, and pulmonary edema occasionally accompanied by hemorrhage. Body condition is usually good to excellent. Cardiac hypertrophy involving the left ventricle and intraventricular septum may also be seen. Microscopic changes are consistent with gross findings and include pulmonary congestion and edema with renal perivenous hemorrhage. Intimal vacuolation and medial hyperplasia of arteries and arterioles have been described in multiple organs, particularly the kidney, spleen, and lung of turkeys with PHS; however, similar lesions can be seen to a lesser extent in tissue of normal turkeys.

Diagnosis is based on history, typical gross lesions, and absence of infectious agents. PHS has several characteristics in

common with aortic rupture (*see* p 2787) and sudden death syndrome of broilers (*see* p 2821). Extensive PHS lesions can resemble aortic rupture, and these two disorders can occur simultaneously in the same flock.

There is no specific treatment. Factors that decrease growth rate and activity also tend to decrease PHS. Reserpine (0.5 ppm feed) decreases PHS, but aspirin (0.005%) or increased calcium has no effect. Reserpine is not listed in the Feed Additive Compendium as approved for use in feed for turkeys.

Increased room temperature and step up/step down lighting programs have also reduced PHS. Activities that increase cardiovascular stress (eg, moving birds, tilling litter, noise) should be minimized, especially between 7 and 15 wk of age. Lower ambient temperatures (55°F [13°C]), intermittent lighting, and leaving toes unclipped increase mortality from PHS. PHS may occur in commercial flocks of healthy male turkeys, regardless of management practices used to prevent its occurrence.

SPONTANEOUS CARDIOMYOPATHY OF TURKEYS

(Round heart disease)

Spontaneous cardiomyopathy of young turkeys is characterized by sudden death due to cardiac arrest and is not related to other cardiomyopathies of poultry.

The exact etiology of spontaneous cardiomyopathy in turkeys is unknown. However, studies using furazolidone to produce dilated cardiomyopathy in turkeys have indicated altered membrane transport resulting in myocardial failure. CK, glycolysis, glycogen, myofibril, Krebs cycle enzymes, fatty acid oxidation, and soluble proteins are all reduced. The calcium-transport ATPase activity of the sarcoplasmic reticulum is increased. This pattern of biochemical changes is consistent with ischemia playing a role in the pathogenesis of spontaneous cardiomyopathy in turkeys.

Although most deaths occur during the brooding period, the ratio of heart weight to body weight of affected birds is increased throughout the growing period. The chronic cardiac insufficiency causes reduced growth rate, resulting in attacks on affected birds by their healthy cohorts. In affected turkeys surviving to market age, body weights are reduced an average of 3 lb (1.4 kg). Some outbreaks of the condition have been associated with hypoxia during incubation of the eggs or during transportation of poults from the hatchery to the brood farm. It is possible that stratification of air in poorly ventilated facilities without circulation fans may similarly contribute to heart damage, with subsequent expression of this disease later in life.

Most deaths from spontaneous cardiomyopathy occur during the first

4 wk of life, with mortality peaking at 2–3 wk. Many poults die suddenly, but some may have ruffled feathers, drooping wings, and a general unthrifty appearance. They may show labored, gasping breathing before death. After 3 wk of age, mortality is sporadic. Characteristically, the affected poult in the first 4 wk of life has a greatly enlarged heart due to dilatation of both ventricles, congested lungs, and a swollen liver. Ascites, anasarca, pulmonary edema, and hydropericardium may be present. In older poults, enlarged hearts are due to marked hypertrophy of the ventricles in addition to dilatation. Histologically, lesions of abnormal hearts are nonspecific and include congestion, damage of the myofibrils of the cardiocytes, and focal infiltration by lymphocytes.

Generally, diagnosis is based on history and gross findings at necropsy; although an ECG can be used, it is of little practical use. Sodium and polychlorinated biphenyls or related compounds may produce similar syndromes.

No treatment is available. Hypoxia during incubation, transportation, or brooding has been associated with increased incidence, and enhanced ventilation during these periods appears to be critical. Practitioners have occasionally noted association of high levels of dietary (or drinking water) copper and increased incidence of spontaneous cardiomyopathy. Good brooding practices may reduce mortality, because overheating has also been postulated to increase the incidence of this disease.

CANDIDIASIS

(Thrush, Crop mycosis, Sour crop)

Candidiasis is a mycotic disease of the digestive tract of various avian species, including chickens, turkeys, and quail caused by *Candida albicans*. It commonly develops after use of therapeutic levels of various antibiotics or when using unsanitary drinking facilities. Lesions are most frequently found in the crop and consist of thickened mucosa and whitish, raised pseudomembranes. The same lesions may be seen in the mouth and esophagus. Occasionally, shallow ulcers and sloughing of necrotic epithelium may be present. Listlessness and inappetence may be the only signs. A presumptive diagnosis may be made on observation of gross lesions. ■ Diagnosis can be confirmed by demonstrat-

ing tissue invasion histologically and by culture of the organism. However, culture alone is not diagnostic of disease, because the yeast-like fungus is commonly isolated from clinically normal birds. Young chicks and poults are most susceptible.

Improving sanitation and minimizing antibiotic use in poultry help reduce the incidence of candidiasis. Candidiasis can be treated or prevented with copper sulfate at 1:2,000 dilution in the drinking water, but its effectiveness is controversial. Nystatin, an antifungal medication, in the feed (220 mg/kg of diet) or drinking water (62.5–250 mg/L with sodium lauryl sulfate, a surfactant, at 7.8–25 mg/L) for 5 days may be effective for the treatment of affected turkeys.

COCCIDIOSIS

Coccidiosis is caused by protozoa of the phylum Apicomplexa, family Eimeriidae. In poultry, most species belong to the genus *Eimeria* and infect various sites in the intestine. The infectious process is rapid (4–7 days) and is characterized by parasite replication in host cells with extensive damage to the intestinal mucosa. Poultry coccidia are generally host-specific, and the different species parasitize specific parts of the intestine. However, in game birds, including quail, the coccidia may parasitize the entire intestinal tract. Coccidia are distributed worldwide in poultry, game birds reared in captivity, and wild birds. (See also CRYPTOSPORIDIOSIS, p 209.)

Etiology: Coccidia are almost universally present in poultry-raising operations, but clinical disease occurs only after ingestion of relatively large numbers of sporulated oocysts by susceptible birds. Both clinically infected and recovered birds shed oocysts in their droppings, which contaminate feed, dust, water, litter, and soil. Oocysts may be transmitted by mechanical carriers (eg, equipment, clothing, insects, farm workers, and other animals). Fresh oocysts are not infective until they sporulate; under optimal conditions (70°–90°F [21°–32°C]) with

adequate moisture and oxygen), this requires 1–2 days. The prepatent period is 4–7 days. Sporulated oocysts may survive for long periods, depending on environmental factors. Oocysts are resistant to some disinfectants commonly used around livestock but are killed by freezing or high environmental temperatures. (See also COCCIDIOSIS, p 203.)

Pathogenicity is influenced by host genetics, nutritional factors, concurrent diseases, age of the host, and species of the coccidium. *Eimeria necatrix* and *Eimeria tenella* are the most pathogenic in chickens, because schizogony occurs in the lamina propria and crypts of Lieberkühn of the small intestine and ceca, respectively, and causes extensive hemorrhage. *E. kofoidi* and *E. legionensis* are the most pathogenic in chukars, and *E. leytiae* is most pathogenic in bobwhite quail. Several *Eimeria* species are pathogenic in pheasants, particularly *E. phasianii* and *E. colchici*. Most species develop in epithelial cells lining the villi. Protective immunity usually develops in response to moderate and continuing infection. True age-immunity does not occur, but older birds are usually more resistant than young birds because of earlier exposure to infection.

Clinical Findings: Signs of coccidiosis range from decreased growth rate to a high percentage of visibly sick birds, severe diarrhea, and high mortality. Feed and water consumption are depressed. Weight loss, development of culls, decreased egg production, and increased mortality may accompany outbreaks. Mild infections of intestinal species, which would otherwise be classed as subclinical, may cause depigmentation and potentially lead to secondary infection, particularly *Clostridium* spp infection. Survivors of severe infections recover in 10–14 days but may never recover lost performance.

The lesions are almost entirely in the intestinal tract and often have a distinctive location and appearance that is useful in diagnosis.

Chickens: *E. tenella* infections are found only in the ceca and can be recognized by accumulation of blood in the ceca and by bloody droppings. Cecal cores, which are accumulations of clotted blood, tissue debris, and oocysts, may be found in birds surviving the acute stage.

E. necatrix produces major lesions in the anterior and middle portions of the small intestine. Small white spots, usually intermingled with rounded, bright- or dull-red spots of various sizes, can be seen on the serosal surface. This appearance is sometimes described as “salt and pepper.” The white spots are diagnostic for *E. necatrix* if clumps of large schizonts can be demonstrated microscopically. In severe cases, the intestinal wall is thickened, and the infected area dilated to 2–2.5 times the normal diameter. The lumen may be filled with blood, mucus, and fluid. Fluid loss may result in marked dehydration. Although the damage is in the small intestine, the sexual phase of the life cycle is completed in the ceca. Oocysts of *E. necatrix* are found only in the ceca. Because of concurrent infections, oocysts of other species may be found in the area of major lesions, misleading the diagnostician.

E. acervulina is the most common cause of infection. Lesions include numerous whitish, oval or transverse patches in the upper half of the small intestine, which may be easily distinguished on gross examination. The clinical course in a flock is usually protracted and results in poor growth, an increase in culls, and slightly increased mortality.

E. brunetti is found in the lower small intestine, rectum, ceca, and cloaca. In moderate infections, the mucosa is pale and disrupted but lacking in discrete foci, and

Gross lesions of *Eimeria tenella* with frank hemorrhaging into cecal pouches in a broiler chicken. Courtesy of Dr. Jean Sander.

may be thickened. In severe infections, coagulative necrosis and sloughing of the mucosa occurs throughout most of the small intestine.

E. maxima develops in the small intestine, where it causes dilatation and thickening of the wall; petechial hemorrhage; and a reddish, orange, or pink viscous mucous exudate and fluid. The exterior of the midgut often has numerous whitish pinpoint foci, and the area may appear engorged. The oocysts and gametocytes (particularly macrogametocytes), which are present in the lesions, are distinctly large.

E. mitis is recognized as pathogenic in the lower small intestine. Lesions are indistinct but may resemble moderate infections of *E. brunetti*. *E. mitis* can be distinguished from *E. brunetti* by finding small, round oocysts associated with the lesion.

E. praecox, which infects the upper small intestine, does not cause distinct lesions but may decrease rate of growth. The oocysts are larger than those of *E. acervulina* and are numerous in affected areas. The intestinal contents may be watery. *E. praecox* is considered to be of less economic importance than the other species.

E. hagani and *E. mivati* develop in the anterior part of the small intestine. The lesions of *E. hagani* are indistinct and difficult to characterize. However, *E. mivati* may cause severe lesions similar to those of *E. acervulina*. In severe infections, *E. mivati* may cause reddening of the duodenum because of denuding of the villi. Some consider these species to be of dubious provenance, but work with molecular diagnostics seems to support their validity.

Turkeys: Only four of the seven species of coccidia in turkeys are considered pathogenic: *E. adenoides*, *E. dispersa*, *E. gallopavonis*, and *E. meleagridis*. *E. innocua*, *E. meleagridis*, and *E. subrotunda* are considered nonpathogenic. Oocysts sporulate within 1–2 days after

expulsion from the host; the prepatent period is 4–6 days.

E. adenoides and *E. gallopavonis* infect the lower ileum, ceca, and rectum. These species often cause mortality. The developmental stages are found in the epithelial cells of the villi and crypts. The affected portion of the intestine may be dilated and have a thickened wall. Thick, creamy material or caseous casts in the gut or excreta may contain enormous numbers of oocysts. *E. meleagridis* chiefly infects the upper and mid small intestine. The lamina propria or deeper tissues may be parasitized, which may result in necrotic enteritis (see p 2802). *E. dispersa* infects the upper small intestine and causes a creamy, mucoid enteritis that involves the entire intestine, including the ceca. Large numbers of gametocytes and oocysts are associated with the lesions.

Common signs in infected flocks include reduced feed consumption, rapid weight loss, droopiness, ruffled feathers, and severe diarrhea. Wet droppings with mucus are common. Clinical infections are seldom seen in poults >8 wk old. Morbidity and mortality may be high.

Game Birds: The Chinese ringneck pheasant, the chukar partridge, and the bobwhite quail, extremely popular as game birds, are reared in large numbers under conditions similar to those of chickens. Losses in these birds from coccidiosis often exceed 50% of a flock. In pheasants, the common species are *E. phasiani*, *E. colchici*, *E. duodenalis*, *E. tetartooimia*, and *E. pacifica*. Chukars are infected by two species: *E. kafoidi* and *E. legionensis*. Bobwhite quail are infected mainly by *E. lettyae*, *E. dispersa*, and *E. coloni*. Treatment and control of these coccidia are similar to that in poultry; however, amprolium appears to be of little use. Monensin and salinomycin are the approved drugs for quail, and lasalocid and sulfadimethoxine/ormetoprim are the approved drugs for chukars.

Ducks: A large number of specific coccidia have been reported in both wild and domestic ducks, but validity of some of the descriptions is questionable. Presence of *Eimeria*, *Wenyonella*, and *Tyzzeria* spp has been confirmed. *T. perniciosus* is a known pathogen that balloons the entire small intestine with mucohemorrhagic or caseous material. *Eimeria* spp also have been described as pathogenic. Some species of coccidia of domestic ducks are considered relatively nonpathogenic. In wild ducks, infrequent but dramatic outbreaks

of coccidiosis occur in ducklings 2–4 wk old; morbidity and mortality may be high.

Geese: The best known coccidial infection of geese is that produced by *E. truncata*, in which the kidneys are enlarged and studded with poorly circumscribed, yellowish white streaks and spots. The tubules are dilated with masses of oocysts and urates. Mortality may be high. At least five other *Eimeria* spp have been reported to parasitize the intestine of geese, but these are of lesser importance.

Diagnosis: The location in the host, appearance of lesions, and the size of oocysts are used in determining the species present. Coccidial infections are readily confirmed by demonstration of oocysts in feces or intestinal scrapings; however, the number of oocysts present has little relationship to the extent of clinical disease. Severity of lesions as well as knowledge of flock appearance, morbidity, daily mortality, feed intake, growth rate, and rate of lay are important for diagnosis. Necropsy of several fresh specimens is advisable. Classic lesions of *E. tenella* and *E. necatrix* are pathognomonic, but infections of other species are more difficult to diagnose. Comparison of lesions and other signs with diagnostic charts allows a reasonably accurate differentiation of the coccidial species. Mixed coccidial infections are common.

A diagnosis of clinical coccidiosis is warranted if oocysts, merozoites, or schizonts are seen microscopically and if lesions are severe. Subclinical coccidial infections may be unimportant, and poor performance may be caused by other flock disorders.

Control: Practical methods of management cannot prevent coccidial infection. Poultry that are maintained at all times on wire floors to separate birds from droppings have fewer infections; clinical coccidiosis is seen only rarely under such circumstances. Other methods of control are vaccination or prevention with anticoccidial drugs.

Vaccination: A species-specific immunity develops after natural infection, the degree of which largely depends on the extent of infection and the number of reinfections. Protective immunity is primarily a T-cell response.

Commercial vaccines consist of live, sporulated oocysts of the various coccidial species administered at low doses. Modern anticoccidial vaccines should be given to day-old chicks, either at the hatchery or on

Release of merozoite from mature schizont, new methylene blue, 100X. Courtesy of Dr. Jean Sander.

the farm. Because the vaccine serves only to introduce infection, chickens are reinfected by progeny of the vaccine strain on the farm. Most commercial vaccines contain live oocysts of coccidia that are not attenuated. The self-limiting nature of coccidiosis is used as a form of attenuation for some vaccines, rather than biologic attenuation. Some vaccines sold in Europe and South America include attenuated lines of coccidia. Research has shown promise for vaccination in game birds.

Layers and breeders maintained on floor litter must have protective immunity. Historically, these birds were given a suboptimal dosage of an anticoccidial drug during early growth, with the expectation that immunity would continue to develop from repeated exposure to wild types of coccidia. This method has never been completely successful because of the difficulty in controlling all the factors affecting reproduction of coccidia under practical conditions. Although anticoccidial drugs have been preferred for protection of these birds, vaccination programs are gaining popularity. Better administration techniques and choice of coccidia strains in the product are improving the feasibility of vaccination in broilers.

Anticoccidial Drugs: Many products are available for prevention or treatment of coccidiosis in chickens and turkeys (see TABLES 1 and 2). Detailed instructions for use are provided by all manufacturers to help users with management considerations and to ensure compliance with regulatory approvals.

Anticoccidials are given in the feed to prevent disease and the economic loss often associated with subacute infection. Prophylactic use is preferred, because most of the damage occurs before signs

become apparent and because drugs cannot completely stop an outbreak. Therapeutic treatments are usually given by water because of the logistical restraints of feed administration. Antibiotics and increased levels of vitamins A and K are sometimes used in the ration to improve rate of recovery and prevent secondary infections.

Continuous use of anticoccidial drugs promotes the emergence of drug-resistant strains of coccidia. Various programs are used in attempts to slow or stop selection of resistance. For instance, producers may use one anticoccidial continuously through succeeding flocks, change to alternative anticoccidials every 4–6 mo, or change anticoccidials during a single growout (ie, a shuttle program). While there is little cross-resistance to anticoccidials with different modes of action, there is widespread resistance to most drugs. Coccidia can be tested in the laboratory to determine which products are most effective. “Shuttle programs,” in which one group of chickens is treated sequentially with different drugs (usually a change between the starter and grower rations), are common practice and offer some benefit in slowing the emergence of resistance. In the USA, the FDA considers shuttle programs as extra-label usage, but producers may use such programs on the recommendation of a veterinarian.

The effects of anticoccidial drugs may be coccidiostatic, in which growth of intracellular coccidia is arrested but development may continue after drug withdrawal, or coccidiocidal, in which coccidia are killed during their development. Some anticoccidial drugs may be coccidiostatic when given short-term but coccidiocidal when given longterm. Most anticoccidials currently used in poultry production are coccidiocidal.

The natural development of immunity to coccidiosis may proceed during the use of anticoccidials in the feed. However, in the production of broilers during a short growout of 37–44 days, this may be of little consequence. Natural immunity is important in replacement layer pullets, because they are likely to be exposed to coccidial infections for extended periods after termination of anticoccidial drugs. Anticoccidial programs for layer and breeder flocks are intended to allow immunizing infection while guarding against acute outbreaks.

Anticoccidials are commonly withdrawn from broilers 3–7 days before slaughter to

meet regulatory requirements and to reduce production costs. Because broilers have varying susceptibility to infection at this point, the risk of coccidiosis outbreaks is increased with longer withdrawal.

Turkeys are given a preventive anticoccidial for confinement-reared birds up to 8–10 wk of age. Older birds are considered less susceptible to outbreaks.

The modes of action of anticoccidial drugs are poorly understood. Some that are better known are described below. Knowledge of mode of action is important in understanding toxicity and adverse effects.

Amprolium is an antagonist of thiamine (vitamin B₁). Rapidly dividing coccidia have a high requirement for thiamine. Amprolium has a safety margin of ~8:1 when used at

TABLE 2 DRUGS FOR PREVENTION OF COCCIDIOSIS IN POULTRY

Drug ^a	Use Level (% in feed)		Withdrawal Time (days)
	Chickens	Turkeys	
Amprolium	0.0125–0.025	0.0125–0.250	0

^a Approved in the USA; compiled from various sources, including, with permission, the *Feed Additive Compendium*, The Miller Publishing Co., 2008. Anticoccidials not approved in the USA but available in various other countries include clazuril, a combination of clopidol plus methylbenzoquate, and various combinations of ionophores with nicarbazin.

^b Up to 10 wk of age.

TABLE 3 DRUGS FOR TREATMENT OF COCCIDIOSIS IN CHICKENS

Drug ^a	Feed or Water	Use Level, Treatment Duration	Withdrawal Time (days)
Amprolium	Water	0.012% 0.024%, 3–5 days; 0.006%, 1–2 wk	0
Chlortetracycline	Feed	0.022% + 0.8% calcium, not more than 3 wk	0
Oxytetracycline	Feed	0.022% + 0.18%–0.55% calcium, not more than 5 days	3
Sodium sulfachloro- pyrazine monohydrate	Water	0.03%, 3 days	4
Sulfadimethoxine	Water	0.05%, 6 days	5
Sulfamethazine (sulfadimidine)	Water	0.1%, 2 days; 0.05%, 4 days	10
Toltrazuril	Water	25 ppm, 2 days	NA ^b

^a Approved in the USA, except for toltrazuril^b Not applicable

the highest recommended level in feed (125–250 ppm). Because amprolium has poor activity against some *Eimeria* spp, its spectrum has been extended by using it in mixtures with the folic acid antagonists ethopabate and sulfaquinoxaline. The primary use of amprolium today is for water treatment during clinical outbreaks.

Clopidol and quinolines (eg, decoquin-ate, methylbenzoate) are coccidiostatic against early development of *Eimeria* spp by inhibiting mitochondrial energy production. Clopidol and quinolines have a broad species spectrum and are sometimes mixed together for synergism. However, resistance may develop rapidly during extended use.

Folic acid antagonists include the sulfonamides, 2,4-diaminopyrimidines, and ethopabate. These compounds are structural antagonists of folic acid or of para-aminobenzoic acid (PABA), which is a precursor of folic acid. (The host does not synthesize folic acid and has no requirement for PABA.) Coccidia rapidly synthesize nucleic acids, accounting for activity of PABA antagonists. Although resistance to antifolate compounds is widespread, they are commonly used for water treatment when clinical signs are already evident. Diaveridine, ornetoprim, and pyrimethamine are active against the protozoan enzyme dihydrofolate reductase. They have synergistic activity with

sulfonamides and often are used in mixtures with these compounds.

Halofuginone hydrobromide is related to the antimalarial drug febrifuginone and is effective against asexual stages of most species of *Eimeria*. It has both coccidiostatic and coccidiocidal effects, but coccidia may become resistant after extended exposure.

The **ionophores** (**monensin**, **salinomycin**, **lasalocid**, **narasin**, **maduramicin**, and **semduramicin**) form complexes with various ions, principally sodium, potassium, and calcium, and transport these into and through biologic membranes. The ionophores affect both extra- and intracellular stages of the parasite, especially during the early, asexual stages of parasite development. Drug tolerance was slow to emerge in chicken coccidia, probably because of the biochemically nonspecific way these fermentation products act on the parasite. Recent surveys suggest that drug tolerance is now widespread, but these products remain the most important class of anticoccidials.

Some ionophores may depress feed consumption when the dosage is above recommended levels. Primarily, this is the result of reduced feed consumption, but the reduced growth may be offset by improved feed conversion.

Nicarbazin was the first product to have truly broad-spectrum activity and has been in common use since 1955. Although not completely understood, the mode of action is thought to be via inhibition of succinate-linked nicotinamide adenine dinucleotide reduction and the energy-dependent transhydrogenase, and the accumulation of calcium in the presence of ATP. Nicarbazin is toxic for layers, causing mottling of egg yolks, decreased egg production, and blanching of brown egg shells. A 4-day withdrawal period is required in broilers. Medicated birds are at increased risk of heat stress in hot weather.

Nitrobenzamides (eg, dinitolmide) exert their greatest coccidiostatic activity against the asexual stages. Efficacy is limited to *E. tenella* and *E. necatrix* unless combined with other products.

Robenidine, a guanidine compound, allows initial intracellular development of coccidia but prevents formation of mature schizonts. It is coccidiostatic when given short term and coccidiocidal long term. Drug resistance may develop during use. A 5-day withdrawal period is needed to eliminate untoward flavor caused by residues in poultry meat.

Roxarsone is an organic arsenical compound. It has significant activity against *E. tenella* and is used in combination with ionophores to improve control of that species. A withdrawal period is required.

Diclazuril and **toltrazuril** are highly effective against a broad spectrum of coccidia. Diclazuril is used mostly for prevention at 1 ppm in the feed, whereas toltrazuril is used primarily for treatment in the water.

CORONAVIRAL ENTERITIS OF TURKEYS

(Bluecomb, Mud fever, Transmissible enteritis)

Coronaviral enteritis is an acute, highly contagious disease of turkeys characterized by depression, anorexia, diarrhea, and decreased weight gain. Mortality may be high, particularly in young poults, but failure to gain body weight in adult birds may be more important economically. The causative agent is turkey coronavirus (TCV), but clinical disease usually is complicated by other enteric viral, bacterial, and protozoal infections.

Epidemiology: Coronaviral enteritis has been identified in turkeys in the USA, Canada, Brazil, Italy, UK, and Australia. The disease has been reported in most turkey-producing regions of the USA. Turkey coronavirus affects turkeys of all ages; however, clinical disease most commonly is seen in young turkeys during the first few weeks of life. Turkeys are believed to be the only natural host for TCV.

TCV is shed in feces of infected birds and spread horizontally through ingestion of feces and feces-contaminated materials. Virus is shed in droppings of turkeys for several weeks after recovery from clinical disease. Infection generally spreads rapidly

through a flock and from flock to flock on the same or neighboring farms. Mechanical movement of the virus may occur by people, equipment, vehicles, and insects. Darkling beetle larvae and domestic house flies are potential mechanical vectors. Wild birds, rodents, and dogs also may serve as mechanical vectors. There is no evidence that TCV is egg transmitted; however, poults may become infected in the hatchery via contaminated personnel and fomites such as egg boxes from infected farms.

Clinical Findings: Clinical signs occur suddenly, usually with high morbidity. Birds exhibit depression, anorexia, decreased water consumption, watery diarrhea, dehydration, hypothermia, and weight loss. Droppings typically are green to brown, watery, and frothy, and may contain mucus and urates. Affected flocks have increased mortality, growth depression, and poor feed conversion. Morbidity generally approaches 100%, but mortality is variable; mortality may be high depending on the age of the birds, concurrent infection, management practices, and weather conditions.

In breeder hens, egg production drops rapidly. Egg quality also is affected; hens

produce white, chalky eggs lacking normal pigmentation.

Lesions: Gross lesions are seen primarily in the intestines. The duodenum and jejunum generally are pale, thin-walled, and flaccid; ceca are distended with gas and watery contents. Emaciation, dehydration, and atrophy of the bursa of Fabricius also may be seen.

In the intestines, microscopic lesions consist of a decrease in villous length and increase in crypt depth; the columnar epithelium changes to a cuboidal epithelium, and these cells exhibit a loss of microvilli. There is a decrease in the number of goblet cells, separation of enterocytes from the lamina propria, and infiltration of the lamina propria with heterophils and lymphocytes.

In the bursa of Fabricius, the normal pseudostratified columnar epithelium is replaced by a stratified squamous epithelium, and intense heterophilic inflammation is seen within and underneath the epithelium.

Diagnosis: Diagnosis generally requires laboratory assistance, because other enteric pathogens of turkeys may cause similar clinical signs and lesions. Laboratory diagnosis is based on virus isolation, electron microscopy, serology, or detection of viral antigens or viral RNA in intestinal tissues, the bursa of Fabricius, or intestinal contents. Preferred clinical samples for diagnostic analyses include serum, intestinal contents, and fresh tissues (intestines and bursa of Fabricius); these samples should be kept cold (on ice at 4°C or frozen) at all times. Coronaviral enteritis

must be distinguished from other enteric viral, bacterial, and parasitic infections, including those caused by astrovirus, rotavirus, reovirus, *Salmonella* spp, and cryptosporidia.

Prevention and Treatment: Prevention is the preferred method to control TCV. No commercial vaccine is available. Infected turkeys shed virus in feces for prolonged periods after recovery; these turkeys, their feces, and the materials their feces contact are potential sources of infection for other susceptible turkeys. Feces from infected turkeys can be carried on a variety of fomites, including clothing, boots, equipment, feathers, and trucks. Other potential vectors, such as wild birds, rodents, dogs, and flies, also may be involved in transmission. Biosecurity measures must be instituted to prevent introduction of TCV via potentially contaminated personnel, fomites, animal and insect vectors, and infected turkeys.

TCV may be eliminated from contaminated premises by depopulation followed by thorough cleaning and disinfection of houses and equipment. After cleaning and disinfection procedures, premises should remain free of birds for a minimum of 3–4 wk.

There is no specific treatment for TCV enteritis. Antibiotic treatment reduces mortality but not growth depression, most likely by controlling secondary bacterial infections. No beneficial effect was seen when glucose, electrolytes, or calf milk replacer was added to drinking water. Effective management procedures to reduce mortality include raising brooder house temperatures and avoiding crowded conditions.

CRYPTOSPORIDIOSIS

Cryptosporidiosis is caused by protozoa (phylum Apicomplexa) that are members of the family Cryptosporidiidae and are related, but distinct, to coccidia of the genera *Eimeria*, *Isospora*, *Sarcocystis*, and *Toxoplasma*. Until recently, it was thought that there were 19 species in the genus *Cryptosporidium*, but research has shown that most are merely species that lack host specificity. Cryptosporidia are parasitic in the intestine of mammals (see p 209), but in birds they are commonly

found in the bursa and in the respiratory tract. Cryptosporidiosis is more severe in turkeys than in chickens and is frequently fatal in quail.

The life cycle of *Cryptosporidium* involves asexual and sexual phases and culminates in oocyst production. In the host, the oocyst forms four sporozoites without sporocysts. The life cycle is not self-limiting, because some oocysts are thin-walled and release sporozoites (after trypsin/bile stimulation) that reinfect

Cryptosporidium on tracheal mucosa of a turkey, H&E, 40 $\times$. Courtesy of Dr. Jean Sander.

adjacent tissues. The endogenous cycle is short (4–7 days), the endogenous stages are small (4–7 μm), and the parasites are just beneath the epithelial cell membranes.

In turkeys and chickens, *Cryptosporidium* have been found in the sinuses, trachea, bronchi, cloaca, and bursa. The

most common clinical signs include diarrhea and dehydration. In addition to diarrhea, the parasites can infect the respiratory tract and lead to coughing, gasping, airsacculitis, and sometimes death. Lungs become gray and wet. Signs may last several weeks.

Diagnosis is by microscopic examination of tissue scrapings or histologic examination of tissues from the bursa, cloaca, and trachea. The small (5 μm) oocysts can be diagnostic but are difficult to see. Concentration of intestinal scrapings using saturated sugar solution and examination by phase-contrast or interference-contrast microscopy may improve visualization. Positive identification should be performed by trained researchers or diagnosticians.

There are no satisfactory control measures except isolation and good sanitation. None of the known anticoccidial drugs is effective against *Cryptosporidium* spp. Unlike *Cryptosporidium* spp. of other mammals, the avian species are not infectious to people.

DUCK VIRAL ENTERITIS

(Duck plague, Anatid herpes, Eendenpest, Entenpest, Peste du canard)

Duck viral enteritis (DVE) is an acute, highly contagious disease of ducks, geese, and swans of all ages, characterized by sudden death, high mortality (particularly among older ducks), and hemorrhages and necrosis in internal organs. It has been reported in domestic and wild waterfowl in Europe, Asia, North America, and Africa, resulting in limited to serious economic losses on domestic duck farms and sporadic, limited to massive die-offs in wild waterfowl. In the USA, considerable losses due to DVE have been reported in the concentrated duck-producing areas located in Long Island, New York.

Members of the family Anatidae (ducks, geese, and swans) are the natural hosts for the virus. There are differences in susceptibility to the virus, with Muscovy ducks being the most susceptible. However, naturally occurring infections have been reported in a variety of domestic ducks such as Pekin, Khaki Campbell, Indian runners, and mixed breeds. The age at infection ranges from 7 days to maturity. The infection has not been reported in other avian species,

mammals, or people and does not pose a zoonotic risk.

Etiology and Pathogenesis: The causative agent of DVE (species Anatid herpesvirus 1) is a member of the family Herpesviridae, subfamily Alphaherpesvirinae, and genus *Mardivirus*. Field strains of this virus display differences in virulence, but all seem to be immunologically identical. The virus is sensitive to lipid solvents and heat (10 min at 56°C [132.8°F]). Significant titer reduction is observed at pH 5, 6, and 10; rapid inactivation occurs at pH 3 and 11.

The virus induces vascular damage, especially in smaller blood vessels, venules, and capillaries. This results in the development of generalized hemorrhages and progressive degenerative changes of parenchymatous organs. Recently, it has been proposed that apoptosis and necrosis of lymphocytes induced by this virus may result in lymphoid depletion and possibly immunosuppression. An immunosuppressive state induced by DVE may also explain

the presence of secondary infections by *Pasteurella multocida*, *Riemerella anatipestifer*, and *Escherichia coli*, which are frequently seen in natural outbreaks of DVE in ducklings.

Epidemiology and Transmission:

The virus is mainly transmitted by direct contact from infected to susceptible ducks or by indirect contact with a contaminated environment. Water seems to be a natural route of viral transmission. Outbreaks are frequent in duck flocks with access to bodies of water cohabited with free-living waterfowl. Parenteral, intranasal, or oral administration of infected tissues can establish experimental infection. A carrier condition is suspected in wild birds. Recovered birds become latently infected carriers and may shed the virus periodically. DVE virus may undergo latency like other herpesviruses, and the trigeminal ganglion seems to be a latency site for the virus. Recovered birds may carry the virus in its latent form, and viral reactivation may be the cause of outbreaks in susceptible wild and domestic ducks.

Clinical Findings: The incubation period is 3–7 days. Sudden high and persistent mortality is often the first sign of the disease. Mortality varies and can be 5%–100%, depending on virulence of the infecting viral strain. Adult ducks usually die in higher proportions than young ones, increasing the economic significance of the disease. Sick birds are unable to stand and show indication of weakness and depression. Photophobia, inappetence, extreme thirst, droopiness, ataxia, nasal discharge, soiled vents, and watery or bloody diarrhea may be seen. Adult ducks may die in good flesh. In contrast, ducklings frequently show dehydration and weight loss, as well as blue beaks and blood-stained vents. Dead males may have prolapse of the penis. In laying flocks, egg production may drop sharply.

Lesions: The lesions are indicative of disseminated intravascular coagulopathy and necrosis of the mucosa and submucosa of the GI tract and lymphoid tissues. Damage of blood vessels throughout the body induces hemorrhages in various tissues or the presence of free blood in body cavities. Petechial and ecchymotic hemorrhages on the heart ("paint-brush" appearance), liver, pancreas, mesentery, and other organs are characteristic. Specific mucosal eruptions, found in the oral cavity, esophagus, ceca, rectum, and cloaca, undergo progressive alterations during the course of the disease. Macular hemorrhages

initially develop into elevated, yellowish, crusted plaques and organize into green, superficial scabs, which may coalesce into large, patchy, diphtheritic membranes. The mucosal lesions align parallel with the longitudinal folds in the esophagus. Hemorrhagic annular bands can be seen in different portions of the intestines, which correspond to necrosis and hemorrhage of the gut-associated lymphoid tissue. In geese, intestinal lymphoid disks are analogous to the annular bands in ducks, and "button-like" ulcers may be seen. Diphtheritic esophagitis may be commonly seen in swans. Lumina of the intestines and gizzard are often filled with blood. The liver is enlarged, pale copper in color, and may have pinpoint surface hemorrhages mixed with white necrotic foci. The pancreas may have petechiation and multifocal necrosis.

The lymphoid organs are severely affected; the spleen may be normal or smaller in size and darkened due to congestion. The thymic lobes may be petechiated, and thymic atrophy has been reported with some strains. The bursa of Fabricius may be severely congested or hemorrhagic. In ducklings, the lesions of the lymphoid tissues are more evident than the lesions in other visceral organs. A lesion that can be easily detected on necropsy is a clear, yellow fluid that infiltrates and discolors the subcutaneous tissues from the thoracic inlet to the upper third of the neck. In mature hens, hemorrhages may be seen in deformed and discolored ovarian follicles, and ruptured yolk and free blood may be found in the abdominal cavity.

Microscopically, eosinophilic intranuclear inclusions may be seen in the epithelial cells of the GI tract and in the thymus, bursa, spleen, esophagus, cloaca, liver, conjunctiva, and Harderian gland. Occasional intracytoplasmic inclusions are also scattered in the epithelial cells of the conjunctiva, esophagus, bursa of Fabricius, and cloaca.

Duck viral enteritis, mottled thymus with multiple petechiae and necrotic focal areas. Courtesy of Dr. Alejandro Banda.

Diagnosis: Presumptive diagnosis is based on disease history and lesions. Definitive diagnosis may require viral isolation or identification of DVE. Different diagnostic protocols based on PCR are available, either by conventional or quantitative real-time PCR. These molecular techniques provide much more rapid and efficient diagnosis of this disease than other methods. The tissues to collect are liver, spleen, esophagus, and portions of small intestine that show suggestive lesions. Isolation of the virus from liver, spleen, or kidney tissues may be attempted in various cell cultures (preferably primary Muscovy duck embryofibroblasts or Muscovy duck embryo liver cultures), duck embryos, or ducklings. Inoculating the chorioallantoic membrane of 9- to 14-day-old embryonated Muscovy duck eggs may result in isolation of the virus, but this method is not as sensitive as IM inoculation of day-old ducklings. Muscovy ducklings are more susceptible than White Pekin ducklings. Neutralization with specific antiserum in these systems confirms the identity of the virus. Fluorescent antibody testing can demonstrate DVE viral proteins. Serologic tests have little value in the diagnosis of acute infections. Serum neutralization tests have been used to monitor exposure to the virus in wildfowl.

Differential diagnoses include duck viral hepatitis, pasteurellosis, necrotic and

hemorrhagic enteritis, trauma, drake damage, and various toxicoses. Newcastle disease, avian influenza, and fowlpox may cause similar lesions but are rarely reported in ducks. Established cases should be reported to the appropriate regulatory agency.

Prevention, Treatment, and Control:

There is no treatment. Contact with wild, free-flying waterfowl and direct or indirect contact with contaminated birds or material (free-flowing water) should be avoided. Control is effected by depopulation, removal of birds from the infected environment, sanitation, and disinfection. Prevention is based on maintenance of susceptible birds in a disease-free environment or immunization. A chicken-embryo-adapted, modified-live virus vaccine has been approved in the USA to immunize domestic ducks in zoological aviaries and by private aviculturists. A 0.5-mL dose is administered SC or IM to domestic ducklings >2 wk old. Breeding flocks should be revaccinated annually. The vaccine can be used in an outbreak, because it elicits rapid protection after vaccination. It is not approved for use in wild ducks. An inactivated vaccine, which appears to be as efficacious as the modified-live vaccine, has not been tested on a large scale and is not currently licensed.

HEXAMITIASIS

Hexamitiasis is an acute, infectious, catarrhal enteritis of turkeys, pheasants, quail, chukar partridges, and peafowl. The highest mortality occurs in birds 1–9 wk old. Natural infection has not been observed in chickens. Pigeons are susceptible to another species of *Spironucleus* (*S columbae*). Hexamitiasis is rare in North America.

Etiology: The causative protozoan parasite in turkeys, *S meleagridis* (formerly *Hexamita meleagridis*) is spindle-shaped; averages $8 \times 3 \mu\text{m}$; and has four anterior, two anterolateral, and two posterior flagella. It has not yet been cultured in experimental media, although it has been grown in the allantoic cavity of developing chicken and turkey embryos. It is transmitted directly by ingestion of contaminated feces and water. Encysted hexamitids are resistant to

environmental conditions outside the bird and, therefore, may be more important in the transmission of the disease. Up to $\frac{1}{3}$ of the recovering birds become carriers and shed parasites in their droppings.

Clinical Findings and Lesions:

Signs of hexamitiasis are nonspecific and include watery diarrhea that may be yellowish later in the disease, dry unkempt feathers, listlessness, and rapid weight loss despite the fact the birds continue to eat. Birds may die in coma or convulsions. Bulbous dilations of the small intestine (especially duodenum and upper jejunum) filled with watery contents are characteristic. The crypts of Lieberkühn contain myriad *S meleagridis*, which attach to the epithelial cells by their posterior flagella.

Diagnosis: Diagnosis of hexamitiasis depends on finding the flagellates by microscopic examination of scrapings of the duodenal and jejunal mucosa. *Spironucleus* spp move with a rapid, darting motion (in contrast to the jerky motion of trichomonads). To avoid contamination of instruments with other cecal protozoa, the duodenum should be opened first. *Spironucleus* spp may be demonstrated in poult that have been dead for several hours if the scrapings are placed in a drop of warm (104°F [40°C]), isotonic saline solution on the slide. Presence of a few *Spironucleus* in birds >10 wk old may be unimportant in terms of the disease but still act as a reservoir of infection.

Prevention and Treatment: Because many birds remain carriers of *Spironucleus*, breeder turkeys and young poults should be raised on separate premises if possible, preferably with separate attendants. Wire platforms should be used under feeders and waterers. Pheasants and quail may also be carriers and should not be raised in the same location as poults. Indirect transmission can occur if affected fecal material is transferred to another location by contaminated equipment or clothing.

There is no effective treatment or vaccine for hexamitiasis, although oxytetracycline (0.22% in the feed for 2 wk) or chlortetracycline (0.022%–0.044% in the feed for 2 wk) may be of some benefit to control secondary infections.

NECROTIC ENTERITIS

Necrotic enteritis is an acute enterotoxemia. The clinical illness is usually very short, and often the only signs are a severe depression followed quickly by a sudden increase in flock mortality. The disease primarily affects broiler chickens (2–5 wk old) and turkeys (7–12 wk old) raised on litter but can also affect commercial layer pullets raised in cages. Early mortality is often related to coccidiosis vaccination programs, with *Eimeria* cycling in these flocks.

Etiology and Pathogenesis: The causative agent is the gram-positive, obligate, anaerobic bacteria *Clostridium perfringens*. It is usually isolated on blood agar, incubated anaerobically at 37°C (98.6°F), on which it produces a double zone of hemolysis. There are two primary *C perfringens* types, A and C, associated with necrotic enteritis in poultry. Toxins produced by the bacteria cause damage to the small intestine, liver lesions, and mortality.

C perfringens is a nearly ubiquitous bacteria readily found in soil, dust, feces, feed, and used poultry litter. It is also a normal inhabitant of the intestines of healthy chickens and turkeys. The enterotoxemia that results in clinical disease most often occurs either after a change in the intestinal microflora or from a condition that results in damage to the intestinal mucosa (eg, coccidiosis, mycotoxicosis, salmonellosis, ascarid larvae). High dietary levels of animal byproducts (eg,

fishmeal), wheat, barley, oats, or rye predispose birds to the disease. Anything that promotes excessive bacterial growth and toxin production or slows feed passage rate in the small intestine could promote the occurrence of necrotic enteritis. In many cases, concurrent coccidiosis (especially *Eimeria maxima*, and *E acervulina* to a lesser extent) is associated with outbreaks in commercial broilers, although recent investigations with NetB-positive isolates have reportedly caused disease without predisposition from *Eimeria* infections.

Clinical Findings and Lesions: Most often the only sign of necrotic enteritis in a flock is a sudden increase in mortality. However, birds with depression, ruffled feathers, and diarrhea may also be seen. The gross lesions are primarily found in the small intestine (jejunum/ileum), which may be ballooned, friable, and contain a foul-smelling, brown fluid. The mucosa is usually covered with a tan to yellow pseudomembrane often referred to as a “Turkish towel” in appearance. This pseudomembrane may extend throughout the small intestine or be localized. The disease usually persists in a flock for 5–10 days, and mortality is 2%–50%.

Diagnosis: A presumptive diagnosis is based on gross lesions and a gram-stained smear of a mucosal scraping that exhibits large, gram-positive rods. Histologic

Mucosal surface of small intestine of a broiler chicken infected with *Clostridium perfringens* (necrotic enteritis). Courtesy of Dr. Billy Hargis.

findings consist of coagulative necrosis of one-third to one-half the thickness of the intestinal mucosa and masses of short, thick bacterial rods in the fibrinonecrotic debris. Isolation of large numbers of *C perfringens*, from intestinal contents that produce the double zone of hemolysis as described above, can confirm the diagnosis. Double zone hemolysis should not be used as the sole criterion for identification of *C perfringens*, because some strains do not produce both toxins responsible for the hemolysis characteristics. Differential media specifically designed for isolation of *C perfringens* is available and may be useful for diagnosis.

Necrotic enteritis must be differentiated from lesions produced by *Eimeria brunetti* and also from ulcerative enteritis. Uncomplicated coccidiosis rarely produces lesions as acute or severe as those seen with necrotic enteritis. Ulcerative enteritis caused by *C colinum* usually produces focal lesions from the distal portion of the small intestine (ileum) to the ceca and is almost always accompanied by hepatic necrosis.

Prevention, Control, and Treatment:

Because *C perfringens* is nearly ubiquitous, it is important to prevent coccidiosis, especially *E acervulina* and *E maxima* infections, as well as changes in the intestinal microflora that would promote its growth. This has traditionally been accomplished by adding antibiotics in the feed such as virginiamycin (20 g/ton feed), bacitracin (50 g/ton feed), and lincomycin (2 g/ton feed), as well as ionophore-class anticoccidial treatments. The move to antibiotic-free feeds has also been associated with markedly increased use of coccidiosis vaccines, resulting in early circulation of mixed *Eimeria* infections that are associated with the resurgence in incidence of necrotic enteritis. Avoiding drastic changes in feed and minimizing the level of fishmeal, wheat, barley, or rye in the diet can also help prevent necrotic enteritis. When higher amounts of wheat, barley, or rye are necessary, use of enzymes for nonstarch polysaccharides in the feed has reduced the level of necrotic enteritis in flocks fed these cereals. Administration of selected probiotics or competitive exclusion cultures has been used successfully to both prevent and treat clinical necrotic enteritis (presumably by preventing proliferation of *C perfringens*).

Treatment for necrotic enteritis is most commonly administered in the drinking water, with bacitracin (200–400 mg/gal. for 5–7 days), penicillin (1,500,000 u/gal. for 5 days), and lincomycin (64 mg/gal. for 7 days) most often used. In each case, the medicated drinking water should be the sole source of water. Moribund birds should be removed promptly, because they can serve as a source of toxicoxis or infection due to cannibalism.

ROTAVIRAL INFECTIONS IN CHICKENS, TURKEYS, AND PHEASANTS

Rotaviral infections are characterized by enteritis and diarrhea in young birds, but chickens have been infected without showing clinical signs.

Avian rotaviruses consist of four distinct serotypes (A–D). Group A rotaviruses

share a common group antigen with mammalian rotaviruses. Group D rotaviruses have been identified only in avian species. The relationships of the other two avian serotypes to mammalian serotypes have not been established. Transmission

is horizontally by the oral route. Egg transmission has not been reported.

Early signs of diarrhea (wet litter), depression, and poor or abnormal appetite can be seen 2–5 days after infection. Dehydration occurs rapidly, and mortality can be as high as 30%–50% in pheasants but is lower in turkeys and chickens. The survivors appear healthy but smaller than normal. Lesions consist of dilated intestines filled with yellowish, frothy, watery contents. Often, the carcass is dehydrated. Mortality is variable and is usually due to dehydration and emaciation or secondary bacterial infections.

Early diarrhea and inappetence that sometimes end with death are indicative but not pathognomonic of rotaviral infection. Fecal samples or intestinal contents can be examined by electron microscopy with negative staining, either

directly or after ultracentrifugation. Numerous rotaviral particles ~70 nm in diameter, with double-shelled capsids, can be seen and are distinguishable from reovirus by their more sharply defined outer edges. For viral isolation in chicken-embryo liver cells or chick kidney cells, fecal material must be treated with trypsin. Isolated rotaviruses belong mostly to serotype A and, in general, do not cause cytopathic effects on primary isolation. The presence of virus can be demonstrated 2–3 days after inoculation by immunofluorescent staining. Reverse transcriptase PCR is currently used to detect the virus in gut contents.

No commercial vaccines are available. Thorough cleaning and disinfection of infected houses is advisable to limit infection. There is no specific treatment.

TRICHOMONOSIS

Trichomonosis in domestic fowl, pigeons, doves, songbirds, and hawks is characterized, in most cases, by caseous accumulations in the throat and usually by weight loss. It has been termed “canker,” “roup,” and, in hawks, “frounce.”

Etiology: Both *Trichomonas gallinae* and a newly recognized species, *T. stableri*, are the causative organisms of trichomonosis. These flagellated protozoa live in the sinuses, mouth, throat, esophagus, liver, and other organs. Trichomonosis is more prevalent among domestic pigeons and wild doves than among domestic fowl, although severe outbreaks have been reported in chickens and turkeys. Some trichomonad strains cause high mortality in pigeons and doves. Hawks may become diseased after eating infected birds and commonly show liver lesions, with or without throat involvement. Pigeons and doves transmit the infection to their offspring in contaminated pigeon milk. Contaminated water is probably the most important source of infection for chickens, turkeys, and songbirds, and the parasite has been shown to survive at least 20 min in distilled water.

Clinical Findings: The disease course of trichomonosis is rapid. The first lesions

appear as small, yellowish areas on the oral mucosa. They grow rapidly and coalesce to form masses that frequently completely block the esophagus and may prevent the bird from closing its mouth. Much fluid may accumulate in the mouth. There is a watery ocular discharge and, in more advanced stages, exudate about the eyes that may result in blindness. Birds lose weight rapidly, become weak and listless, and sometimes die within 8–10 days. In chronic infections, birds appear healthy, although trichomonads can usually be demonstrated in scrapings from the mucous membranes of the throat.

Lesions: The bird may be riddled with caseous, necrotic foci. The mouth and esophagus contain a mass of necrotic material that may extend into the skull and sometimes through the surrounding tissues of the neck to involve the skin. In the esophagus and crop, the lesions may be yellow, rounded, raised areas, with a central conical caseous spur, often referred to as “yellow buttons.” The crop may be covered by a yellowish, diphtheritic membrane that may extend to the proventriculus. The gizzard and intestine are not involved. Lesions of internal organs are most frequent in the liver; they vary from a few small, yellow areas of necrosis to almost complete replacement of liver tissue by caseous necrotic debris. Adhesions

and involvement of other internal organs appear to be contact extensions of the liver lesions.

Diagnosis: Lesions of trichomonosis are characteristic but not pathognomonic; those of pox, fungal disease, *Salmonella*, and other infections can be similar. Trichomonosis has sometimes been confused with histomoniasis (see p 2835) because of the similarity in liver lesions. Diagnosis should be confirmed by microscopic examination of a smear of mucus or fluid from the throat to demonstrate the presence of trichomonads. Trichomonads can be cultured easily in various artificial media such as Diamond's media, 0.2% Loeffler's dried blood serum in Ringer's solution, or a 2% solution of pigeon serum in isotonic salt solution. Good growth is obtained at 98.6°F (37°C). Antibiotics may be used to reduce bacterial contamination.

Control: Because trichomonads in pigeons are so readily transmitted from parent to offspring in the normal feeding process, chronically infected birds should be separated from breeding birds. In pigeons, recovery from infection with a less virulent trichomonad strain appears to provide some protection against subsequent attack by a more virulent strain. Successful treatments include carnidazole (10 mg/kg body wt), metronidazole (60 mg/kg body wt), and dimetridazole (50 mg/kg body wt, PO; or in the drinking water at 0.05% for 5–6 days). None of these drugs is approved for use in birds in the USA, but they could be used in non-food-producing birds by veterinary prescription. Bird feeders and waterers should be cleaned regularly and if an outbreak of trichomonosis is documented or suspected, feeders and waterers should be removed for ~2 wk and cleaned with a 10% bleach solution.

ULCERATIVE ENTERITIS

(Quail disease)

Ulcerative enteritis was first diagnosed in bobwhite quail (*Colinus virginianus*). It also affects chickens, turkeys, pheasants, grouse, and other gallinaceous birds. The disease has also been reported in pigeons and psittacine birds. In Japanese quail (*Coturnix coturnix japonica*), only experimentally induced cases have been reported in highly inbred populations. An ulcerative enteritis-like disease is caused by *Clostridium perfringens* in *Coturnix* quail. Ulcerative enteritis occurs worldwide and may be acute or chronic.

Etiology, Epidemiology, and Pathogenesis: *Clostridium colinum* is the etiologic agent. It is an anaerobic, fastidious to culture, gram-positive, spore-forming, slightly curved rod, ~1 × 3–4 μm wide, with subterminal, oval spores. In chickens, the disease is a complex that is linked to stress, coccidiosis, infectious bursal disease, and other predisposing factors. To induce experimental disease in bobwhite quail, >10⁶ viable bacterial cells must be administered PO; chickens inoculated at the same levels are not affected.

Birds that develop chronic ulcerative enteritis or that have recovered from the disease remain carriers. Infection can be

introduced by flies feeding on contaminated fecal material or by recovered carrier birds. Infected birds shed the bacterium in their droppings. Bobwhite quail are the most susceptible to this highly contagious disease. Most cases are reported in captive populations of bobwhite quail, suggesting that management plays a role in the incidence. *C. colinum* spores can survive in the premises for months. *Clostridium* spp have been isolated from water samples obtained from drinker pipes in which biofilm and mineral deposits were present.

After oral infection, the bacterium adheres to the intestinal villi, producing enteritis and ulcers in portions of the small intestine and upper large intestine. Bacilli migrate to the liver via portal circulation, producing necrotic foci that later coalesce into extensive hepatic necrosis. Infarcts of the spleen are common. Stained smears of the lesions reveal the rod-shaped *C. colinum* microorganism. Although toxigenicity tests in mice have been negative, the role of an in situ-produced toxin in the pathogenesis has been suggested but not demonstrated.

Clinical Findings: In susceptible bobwhite quail, sudden death occurs without signs or weight loss and is up

to 100% mortality in just 2–3 days. Acute lesions include hemorrhagic enteritis of the duodenum. In chickens and other game birds, the course of the disease is less severe and is accompanied by anorexia. Signs are similar to those seen in coccidiosis: depressed, listless birds with humped backs, ruffled feathers, diarrhea, and sometimes bloody or watery white droppings, especially in quail in the prolonged course. Chickens recover within 2–3 wk, and mortality rarely exceeds 10%.

Lesions: In early disease stages, the most common lesions include small, round ulcers surrounded by hemorrhages in the small intestine, ceca, and upper large intestine. Small ulcers later coalesce to form larger, sometimes perforating ulcers, producing local or diffuse peritonitis. The presence of blood in the gut resembles coccidiosis. Characteristic yellow to gray necrotic foci are the predominant lesions in the hepatic parenchyma. Splenomegaly with hemorrhages and necrotic areas may be present.

Diagnosis: Gross postmortem lesions, including intestinal ulcerations and yellow to gray necrotizing lesions in the liver, assist in diagnosis. *C. colinum* can be seen in gram-stained smears of the liver and intestinal lesions. In bacteremic birds, the microorganisms can also be found in blood and spleen smears. In chickens, differentiating ulcerative

enteritis from coccidiosis (see p 2791) may be difficult, because both diseases may be present simultaneously. Necrotic enteritis (see p 2802) and histomoniasis (see p 2835) may also present a diagnostic problem, but the hepatic lesions of ulcerative enteritis help differentiate it from these diseases. *C. colinum* can be isolated from liver samples cultured in strict anaerobic conditions in prerduced blood glucose-yeast horse plasma medium. A fluorescent antibody test has been used to accurately diagnose ulcerative enteritis. PCR assay has also been reported as an effective diagnostic test.

Prevention, Treatment, and Control:

Bacitracin in the feed at 200 g/ton is used for prevention in quail. Streptomycin (0.006%) and furazolidone (0.02%) in the feed are effective to treat the disease. Prevention must start with good management practices (eg, avoiding the introduction of new birds into existing flocks). High population density is a predisposing factor. The use of cages is recommended in quail breeding. Sick and dead birds should be removed promptly. Total cleanup between flocks, pest control in and around the premises, and periodic treatment of watering systems with innocuous chemicals that dissolve mineral and or biofilm build-up are good preventive measures.

AVIAN CAMPYLOBACTER INFECTION

Campylobacteriosis is a significant enterocolitis of people frequently acquired through consumption of undercooked poultry meat contaminated with *Campylobacter jejuni*. It is the leading bacterial cause of sporadic enteritis in developed countries. It can also be acquired from handling backyard poultry as well as diarrheic companion animals and from contaminated water. The organism colonizes the intestine of chickens, turkeys, and waterfowl but is generally nonpathogenic in birds. Some strains of *C. jejuni* have been reported to cause enteritis and death in newly hatched chicks and poults; however, it has not been possible to satisfy Koch's postulates and reproduce the syndrome previously termed "avian

vibronic hepatitis" by administering isolates of *C. jejuni* to chickens.

Commercial poultry and free-living birds are natural reservoirs of the thermophilic campylobacters (*C. jejuni*, *C. coli*, and *C. lari*) and other poorly defined species. It is estimated that more than half of all commercial broiler and turkey flocks harbor *C. jejuni*, although the prevalence can vary from 0% to 100% depending on season (lowest in fall and winter and highest in summer). The organism has been isolated from numerous birds, including Columbidae and domestic and free-living Galliformes and Anseriformes.

C. jejuni has been found in all areas of commercial poultry production. Isolation of the organism is a function of surveillance

and ability of laboratory personnel to culture and identify *Campylobacter* spp.

Etiology and Epidemiology: *C. jejuni* is the predominant species associated with foodborne infection derived from poultry. *C. coli* and *C. lari* can also be recovered from the intestinal tract of poultry and have also been implicated in foodborne infection.

Environmental contamination is probably the most common source of infection for poults, chicks, and ducklings. Litter can remain infective for long periods, subject to at least a 10% moisture level and neutral pH. Exposed chicks and poults become colonized and can continue to excrete *C. jejuni* for their lifetimes. Contaminated water may introduce infection into poultry flocks, and nonchlorinated water derived from a dam, river, or shallow well should be regarded as a possible source. Rats, mice, wild birds, darkling beetles, and houseflies can infect flocks; equipment and footwear contaminated with feces from an infected source may also serve as a vehicle of transmission. Once *C. jejuni* has been introduced into the environment, rapid transmission within the flock occurs, with subsequent colonization of a high proportion of exposed breeders, commercial-meat, or laying-strain poultry. Some strains of *Campylobacter* can be transmitted vertically, either on the surface of eggs or by transovarial transmission. It has been isolated from the reproductive tracts of hens and roosters.

Clinical Findings and Lesions: Many chicks are colonized with *Campylobacter* spp early in life with no associated clinical signs or pathology.

Most chicks display no lesions associated with *Campylobacter* infection. Some studies have reported that challenged chicks may exhibit distention of the jejunum, disseminated hemorrhagic enteritis, and in some cases, focal hepatic necrosis. Microscopic lesions of infected chicks include edema of the mucosa of the ileum and cecum with *C. jejuni* in the brush border of enterocytes. Mononuclear infiltration of the submucosa and villous atrophy occur, with intraluminal accumulation of mucus, erythrocytes, and mononuclear and polymorphonuclear cells. However, infected flocks seldom exhibit increased mortality rates or decreased feed conversion. It is unclear whether these findings represent a true clinical syndrome in chicks, because challenge studies frequently result in no lesions.

Diagnosis: Fecal specimens should be collected using swabs, then placed in Cary-Blair transport medium. Alternatively, cecal droppings can be collected into sterile laboratory sampling bags and packed on ice. Enrichment culture of specimens in semisolid motility medium facilitates isolation when small numbers of *C. jejuni* are present. *Campylobacter* can be cultured on many different selective media, but commonly available formulations contain *Brucella* agar base and bovine blood with as many as seven antibiotics that inhibit overgrowth of Enterobacteriaceae. They also can be cultured on blood agar by selective filtration; bacteria in a 1/10 diluted fecal sample are allowed to penetrate a filter (0.45 µm pores) placed on the surface of a blood agar plate. After the liquid is absorbed into the plate, the filter is removed. Thermophilic *Campylobacter* spp should be cultured at 42°C under humid, microaerophilic conditions (85% nitrogen, 10% carbon dioxide, and 5% oxygen) for 48 hr. Some strains require a hydrogen-enriched atmosphere (5%). *Campylobacter* spp of significance in poultry are oxidase- and catalase-positive, indole-negative, and reduce selenite. The thermophilic species may be characterized on the basis of hippurate hydrolysis; nalidixic acid sensitivity is no longer reliable because of the increasing prevalence of fluoroquinolone-resistant *C. jejuni*. The Penner or Lior serotyping schemes can be used to classify *C. jejuni* ribotyping, or pulsed-field gel analysis can distinguish among various *C. jejuni* isolates.

Control and Prevention: Because *C. jejuni* is not found as a specific pathogen under commercial conditions, treatment of poultry flocks is not a consideration. If *C. jejuni* is considered a problem in companion bird aviaries or in exotic species, antibiotics such as erythromycin can be administered in drinking water. Galliformes should receive a dosage of 10–30 mg/kg for 4 consecutive days, and Psittaciformes and exotic birds should be medicated at 30–40 mg/kg. Because of the zoonotic risk associated with *C. jejuni* and its ability to rapidly develop antibiotic resistance, antibiotics should be used with caution in companion birds. Fluoroquinolones and erythromycins are the classes of antimicrobials used to treat people for campylobacteriosis.

Preharvest prevention of *Campylobacter* infection in commercial species is based on strict biosecurity, decontamination of housing between successive flocks,

exclusion of rodents and wild birds, and insect eradication. Chlorination of drinking water to 2 ppm and operation of farms on a strict "all-in/all-out" basis occasionally reduces the prevalence of infection. In the context of commercial production in the USA where earth-floored housing is used and litter is recycled, preharvest control of *C. jejuni* is impractical. Innovative methods of prevention, such as competitive exclusion, bacteriophage therapy, bacteriocins, and the use of vaccines, are under intensive investigation. Withholding feed from broilers and turkeys for at least 12 hr before slaughter and thorough decontamination of transport coops and modules reduce fecal contamination and lower the level of *C. jejuni* introduced into processing plants.

Zoonotic Risk: *C. jejuni* is a major source of foodborne enteritis in people; contaminated, undercooked poultry is responsible for >50% of cases investigated. The condition was recognized in the mid-1970s, and the significance of the organism has become apparent with improved methods of isolation and identification. Nonchlorinated ground water, unpasteurized milk, young diarrheic pets, and contaminated beef and pork products are also responsible for infection of people.

Improved washing of carcasses, use of counter-flow scalding, elimination of

immersion chillers, and reduction in manual handling by installation of advanced automated equipment can reduce *C. jejuni* contamination on poultry meat. Chemical disinfectants, such as chlorine, peracetic acid with hydrogen peroxide, and trisodium phosphate, glutaraldehyde and succinic acid, and organic compounds, such as lactic and acetic acids, may effectively reduce *C. jejuni* on poultry carcasses in the processing plant. Some research indicates that bacteriophages and bacteriocins may also be useful. However, the regulations regarding chemical or biological sanitizers that can be used in processing plants and the performance standards for *Campylobacter* in the plant are currently in flux.

Gamma irradiation at levels of 1–3 kGy effectively eliminates *C. jejuni* from poultry carcasses and products. Irradiation has been endorsed by a number of international health agencies, but irradiated foods are not widely available in the USA because of consumer concerns. The risk of foodborne *C. jejuni* infection can be reduced through cooking of poultry to achieve a core temperature of 74°C for 1 min. Concurrent hygienic storage, handling, and preparation are necessary to prevent contamination of prepared foods, work surfaces, and utensils by raw poultry and other meats.

AVIAN CHLAMYDIOSIS

(Psittacosis, Ornithosis, Parrot fever)

Avian chlamydia can be an inapparent subclinical infection or acute, subacute, or chronic disease of wild and domestic birds characterized by respiratory, digestive, or systemic infection. Infections occur worldwide and have been identified in at least 460 avian species, particularly caged birds (primarily psittacines), colonial nesting birds (eg, egrets, herons), ratites, raptors, and poultry. Among poultry, turkeys, ducks, and pigeons are most often affected. The disease is a significant cause of economic loss and human exposure in many parts of the world.

Etiology and Epidemiology:

Chlamydia psittaci, formerly renamed *Chlamydophila psittaci*, is an obligate intracellular bacterium. All strains of

chlamydia share an identical genus-specific antigen in their lipopolysaccharide but often differ in the composition of other cell-wall antigens, thus providing a basis for serotypic identification. Eight serotypes are recognized; of these, six (A–F) infect avian species and are distinct from mammalian *Chlamydia* serotypes. More recently, strains of *C. psittaci* have been classified using genetic differences in the *omp1* gene into nine genotypes. Seven of these (A, B, C, D, E, F, and E/B) are found in avian species and usually correspond to the equivalent serotype. Each avian serotype/genotype tends to be associated with certain types of birds (see TABLE 4). The same serotype/genotype may cause mild disease or asymptomatic infection in one species but severe or fatal disease in

another species. Serotype A and D are highly virulent for turkeys and can cause mortality of $\geq 30\%$. Serotypes B and E are most frequently recovered from wild birds. Avian serotypes are capable of infecting people and other mammals.

Transmission is by the fecal-oral route or by inhalation. Respiratory discharge or feces from infected birds contain elementary bodies that are resistant to drying and can remain infective for several months when protected by organic debris (eg, litter and feces). Airborne particles and dust spread the organism. After inhalation or ingestion, elementary bodies attach to mucosal epithelial cells and are internalized by endocytosis. Elementary bodies within endosomes in the cell cytoplasm inhibit phagolysosome formation and differentiate into metabolically active, noninfectious reticulate bodies that divide and multiply by binary fission, eventually forming numerous infectious, metabolically inactive elementary bodies. Newly formed elementary bodies are released from the host cell by lysis. The incubation period is typically 3–10 days but may be up to several months in older birds or after low exposure. Host and microbial factors, route and intensity of exposure, and treatment determine clinical course.

Possible sources of *C psittaci* include infected birds, asymptomatic carriers, vertical transmission from infected hens, infected mammals, and contaminated environments. Stressors (eg, transport, crowding, breeding, cold or wet weather, dietary changes, or reduced food availability) and concurrent infections, especially

those causing immunosuppression, can initiate shedding in latently infected birds and cause recurrence of clinical disease. Carriers often shed the organism intermittently for extended periods. Persistence of *C psittaci* in the nasal glands of chronically infected birds may be an important source of organisms.

Longterm inapparent infections lasting for months to years are common and are considered the normal *Chlamydia*-host relationship. The prevalence of infection varies considerably between species and by geographic location. Infection is endemic in commercial turkey flocks; no clinical signs or mild respiratory signs and low mortality are the common presentations. Outbreaks are rare. Although chickens are relatively resistant to clinical disease, asymptomatic infection is frequent. Epidemiologic studies report prevalence varying from 10% to $>90\%$ using serology, culture, or PCR detection; 3%–50% of surveyed wild avian populations may be seropositive.

Clinical Findings and Lesions: Severity of clinical signs and lesions depends on the virulence of the organism, infectious dose, stress factors, and susceptibility of the bird species; asymptomatic infections are common. Nasal and ocular discharge, conjunctivitis, sinusitis, green to yellow-green droppings, fever, inactivity, ruffled feathers, weakness, inappetence, and weight loss can be seen in clinically affected birds. Clinical pathology test results vary with the organs most affected and severity of the disease. Hematologic changes most

+ = Genotype less commonly associated with this bird species or group.

often present are anemia and leukocytosis with heterophilia and monocytosis. Plasma bile acids, AST, LDH, and uric acid may be increased. A radiograph or a laparoscopy may reveal an enlarged liver and spleen and thickened airsacs. Necropsy findings in acute infections include serofibrinous polyserositis (airsacculitis, pericarditis, perihepatitis, peritonitis), pneumonia, hepatomegaly, and splenomegaly. Multiple tan to white to yellow foci and/or petechial hemorrhages can be seen in the liver and spleen. Similar lesions are seen in other systemic bacterial infections and are not specific for avian chlamydiosis. Multifocal necrosis in the liver and spleen is associated with small granular, basophilic intracytoplasmic bacterial inclusions in multiple cell types; occasional heterophils; and increased mononuclear cells (macrophages, lymphocytes, plasma cells) in hepatic sinusoids and splenic sinuses. Necrosis results from direct cell lysis or vascular damage. The latter is also the source of the generalized serofibrinous exudate. In chronic infections, enlargement and discoloration of the spleen or liver may be noted. Necrosis and bacterial inclusions are not seen, but the mononuclear cell response is present in these birds. Lesions are usually absent in latently infected birds, even though *C psittaci* is often being shed.

Diagnosis: Because of the variety of clinical presentations and common occurrence of latently infected carriers, no single diagnostic test can reliably determine infection. Procedures to detect the organism or antibodies are used. In general, the more acute the disease, the greater the number of infective organisms and the easier it is to make a diagnosis. When birds are acutely ill, clinical findings, including hematology, clinical chemistries, and

radiology or typical gross lesions are adequate for a tentative diagnosis.

The combination of a serologic and an antigen detection test, especially PCR, or culture, is a practical diagnostic scheme to confirm chlamydiosis. In live birds, the preferred sample for bacterial culture or PCR is a single conjunctival, choanal, or cloacal swab. Multiple samples collected throughout 3–5 days are recommended for detection of intermittent shedding by asymptomatic birds.

Antibodies may or may not be detectable depending on the test used and on the level and stage of infection. Interpretation of titers from single serum samples is difficult. A 4-fold increase in titers between paired acute and convalescent samples is diagnostic, and high titers in a majority of samples from several birds in a population are sufficient for a presumptive diagnosis. Serologic methods include direct and modified direct complement fixation, elementary body agglutination, antibody ELISA, and indirect immunofluorescence. The elementary body agglutination test detects IgM and is useful to determine recent infection. The complement fixation methods are more sensitive than agglutination methods. High antibody titers may persist after treatment and complicate evaluation of subsequent tests.

Antigen detection methods include immunohistochemistry (eg, immunofluorescence, immunoperoxidase), ELISA, and PCR. ELISA kits developed for detection of *Chlamydia trachomatis* in people are available commercially and are relatively inexpensive. Their exact specificity and sensitivity for detection of *C psittaci* is most often unknown; they appear to have good specificity but somewhat low sensitivity. These kits are most useful when birds are clinically ill. PCR is the most sensitive and specific test, but results may differ between laboratories because of the lack of standardized PCR primers and laboratory method variations. False-positive results are a concern with PCR, because cross-contamination can occur relatively easily. The organism can also be identified in impression smears of affected tissues (eg, liver, spleen, and lung). Chlamydiae stain purple with Giemsa and red with Macchiavello and Gimenez stains.

Immunohistochemistry is usually more sensitive than the histochemical stains mentioned above for detecting bacteria in tissue.

Confirmation requires isolation and identification of *C psittaci* in chick embryo or cell cultures (BGM, L929, Vero) at a

Marked hepatomegaly in an ornate lorikeet (*Trichoglossus ornatus*) with chlamydiosis. Courtesy of Dr. A. J. Van Wetters.

qualified laboratory. Cloacal, choanal, oropharyngeal, conjunctival, or fecal swabs (in a special *Chlamydia* transport media) from live birds, or tissues (liver and spleen preferred) from dead birds should be refrigerated and submitted promptly to the laboratory. Freezing, drying, improper handling, and improper transport media can affect viability. The laboratory should be contacted for directions to submit samples. Concurrent infections with other, more easily diagnosed diseases (eg, colibacillosis, pasteurellosis, herpesvirus infections, mycotic diseases) may mask chlamydial infection. Laboratory and clinical findings should be correlated. Chlamydiosis must be distinguished from other respiratory and systemic diseases of birds.

Prevention and Treatment: Human and avian chlamydiosis is a reportable disease; state and local governmental regulations should be followed wherever applicable. No effective vaccine for use in birds is available. Treatment prevents mortality and shedding but cannot be relied on to eliminate latent infection; shedding may recur. Tetracyclines (chlortetracycline, oxytetracycline, doxycycline) are the antibiotics of choice. Drug resistance to tetracyclines is rare, but reduced sensitivity requiring higher dosages is becoming more common. Tetracyclines are bacteriostatic and effective only against actively multiplying organisms, making extended treatment times (from 2–8 wk, during which minimum-inhibitory concentrations in blood must be consistently maintained) necessary. When tetracyclines are administered orally, additional sources of dietary calcium (eg, mineral block, supplement, cuttle bone) should be reduced to minimize interference with drug absorption.

Outbreaks of clinical disease in poultry flocks are not common. Treating infected flocks with chlortetracycline at 400–750 g/ton of feed for a minimum of 2 wk has effectively decreased potential risk of infection for plant employees. The medicated feed must be replaced by nonmedicated feed for 2 days before slaughter and processing. Calcium supplementation must be withheld during treatment with chlortetracycline, with calcium concentration in the feed reduced to $\leq 0.7\%$. Medicated feed should be provided for 45 days if elimination of the organism is attempted. Use of some tetracycline antibiotics and doxycycline in poultry is prohibited, and state regulations should be followed. Persistence of

oxytetracycline residues in eggs of laying hens is 9 days, and persistence of doxycycline residues is 26 days after administration at 0.5 g/L for 7 days.

In pigeons and companion birds, use of chlortetracycline-medicated feeds for 45 days was historically a standard recommendation for imported birds (see p 1897). Difficulties in palatability of the feed itself or the high level of antibiotic necessary for adequate blood levels have limited its use. Doxycycline is the current drug of choice, because it is better absorbed, has less affinity for calcium, better tissue distribution, and a longer half-life than other tetracyclines. Doxycycline added to feed or water can also result in adequate blood levels and has less effect on normal intestinal flora than does chlortetracycline. The dosage and duration of the treatment varies between species. Protocols derived from controlled studies performed in the particular species treated should be used when available (see p 1897). See also information in the Compendium of Measures To Control *Chlamydophila psittaci* Infection Among Humans (Psittacosis) and Pet Birds (Avian Chlamydiosis), 2010, National Association of State Public Health Veterinarians (NASPHV). When specific information is lacking, an empiric starting dosage of 400 mg/L of water, or 25–50 mg/kg/day, P●, has been suggested.

Appropriate biosecurity practices are necessary to control the introduction and spread of chlamydiae in an avian population. Minimal standards include quarantine and examination of all new birds, prevention of exposure to wild birds, traffic control to minimize cross-contamination, isolation and treatment of affected and contact birds, thorough cleaning and disinfection of premises and equipment (preferably with small units managed on an all-in/all-out basis), provision of uncontaminated feed, maintenance of records on all bird movements, and continual monitoring for presence of chlamydial infection.

The organism is susceptible to heat (it may be destroyed in <5 min at 56°C) and most disinfectants (eg, 1:1,000 quaternary ammonium chloride, 1:100 bleach solution, 70% alcohol, etc) but is resistant to acid and alkali. It may persist for months in organic matter such as litter and nest material, but thorough cleaning before disinfection is necessary.

Zoonotic Risk: Avian chlamydiosis is a zoonotic disease that can affect people after

exposure to aerosolized organisms shed from the digestive or respiratory tracts of infected live or dead birds or by direct contact with infected birds or tissues. Human disease most often results from exposure to pet psittacines and can occur even if there is only brief contact with a single infected bird. Other persons in close contact with birds such as pigeon fanciers, veterinarians, farmers, wildlife rehabilitators, zoo keepers, and employees in slaughtering and processing plants or hatcheries are also at risk. Recent studies showed that zoonotic transmission of

C. psittaci in poultry industry workers is likely underestimated. Precautions should be taken when examining live or dead infected birds to avoid exposure (eg, dust mask and plastic face shield or goggles, gloves, detergent disinfectant to wet feathers, and fan-exhausted examining hood).

Some individuals, especially pregnant women and those with impaired immunity, are more susceptible than others. The illness in people is usually respiratory and varies from flu-like symptoms to systemic disease with pneumonia and possibly endocarditis and encephalitis.

AVIAN NEPHRITIS VIRAL INFECTIONS

Avian nephritis viral infections are contagious infections of chickens characterized by renal damage and visceral urate deposits, growth retardation, and limited mortality (0–10%). They are seen mainly in chickens <7 days old, but interstitial nephritis can be seen in chicks as old as 4 wk. These infections have been reported worldwide. Subclinical infections are common and have been detected by serologic surveys in some SPF flocks and in turkeys.

Etiology and Transmission: The causal viruses are avian nephritis viruses (ANVs, which are astroviruses), some of which were previously recognized as enterovirus-like viruses (ELVs). There is some evidence that a taxonomically distinct astrovirus, chicken astrovirus (CAstV), also causes kidney disease and growth retardation. The descriptions below relate to ANV only. Strains of ANV vary in virulence and in antigenicity. Transmission occurs by direct or indirect contact. Indirect evidence suggests that egg transmission may occur. Infection can be transmitted by oral administration of virus to day-old birds. Virus is consistently isolated from the kidneys or feces during the first 10 days after infection.

Clinical Findings: Clinical signs vary from none to mortality resulting from kidney disease or severe growth retardation. Diarrhea and growth retardation are common in broilers. Outbreaks with mortality of 0–10% can occur in chicks newly hatched to as old as 7 days; cardinal necropsy findings are renal damage and

visceral urate deposits (baby chick nephropathy).

Lesions: Nephritis is a common necropsy finding. Gross and microscopic lesions are often seen in the kidneys. Swelling, paleness, or yellowish discoloration with excessive urate deposition is frequent. Histologic lesions consist of a degeneration of the epithelial cells with infiltration of granulocytes, interstitial lymphocyte infiltration, and moderate fibrosis. In the latter stages, lymphoid follicles develop.

Some ANVs, formerly known as ELVs, induce only intestinal lesions varying from decreased length of the microvillus border to total desquamation of the intestinal epithelium.

Diagnosis: Nephropathogenic strains of infectious bronchitis virus (see p 2909) and CAstV isolates also cause interstitial nephritis. Therefore, when nephritis is diagnosed, it is necessary to isolate the causative agent.

ANV and related viruses may be isolated by inoculation of suspected material (kidney or rectal contents) in the yolk sac of SPF chick embryos and in chick kidney cells. However, many ANVs are difficult to isolate. The best way to detect ANV is by reverse transcriptase (RT)-PCR or real-time, quantitative RT-PCR of kidney or gut content samples. These tests are designed to detect multiple strains and allow quick differentiation from other viruses.

Serologic diagnosis can be made using direct or indirect immunofluorescence,

seroneutralization, or ELISA tests, but these may detect only a limited number of strains of ANV because of its high antigenic diversity.

Treatment and Prevention: There is no effective treatment. General hygienic precautions are the only applicable preventive measures.

AVIAN SPIROCHETOSIS

(Avian borreliosis)

Avian spirochetosis is an acute, febrile, septicemic, bacterial disease that affects a wide variety of birds.

Etiology, Epidemiology, and Transmission: The causal organism, *Borrelia anserina*, is an actively motile spirochete, $\sim 0.2\text{--}0.3\ \mu\text{m} \times 8\text{--}20\ \mu\text{m}$, and consists of 5–8 loosely arranged coils. Cultivation in vitro is difficult. *Borrelia* will grow on Barbour-Stoenner-Kelly medium but loses virulence after 12 passages. It can also be propagated in embryonating duck or chick embryos or in young ducks or chicks.

Spirochetosis is found in temperate or tropical regions, wherever the biologic vectors are found. The most common vector is *Argas persicus*, the “cosmopolitan” fowl tick, but other *Argas* spp transmit the bacteria in different geographic areas. In the western USA, a highly efficient vector is *A. sanchezi*.

Diverse immunologic and serologic types of *B. anserina* have been demonstrated in many areas. Recovery from one type confers solid immunity against the homologous types for ≥ 1 yr, but not against heterologous strains. Relapses, reported for some human *Borrelia* infections, are unknown in *B. anserina* infection of birds. Therefore, any reinfection can be attributed to a heterologous type.

Generally, an infected *Argas* tick can transmit the bacteria at every feeding and maintains the infection throughout larval, nymphal, and adult stages. The ticks also transmit the infection transovarially, ie, the F_1 larvae are infective. Ticks remain infected despite feeding on chicks hyperimmune to *B. anserina* or on chicks with high blood levels of chemotherapeutic agents effective against *Borrelia*. Other vectors (lice, mosquitoes, some species of ticks, inanimate objects) can transmit the spirochete mechanically to a susceptible host whenever the piercing apparatus becomes contaminated with blood that

contains *Borrelia*. Ingestion of bile-stained fecal droppings containing the spirochete, contamination of feed or water, and cannibalism during spirochetemia can result in infection. After the bite of an infected tick, the incubation period is $\sim 3\text{--}12$ days.

Clinical Findings: Signs are highly variable, depending on the virulence of the spirochete, and may be absent. Signs include listlessness, depression, somnolence, moderate to marked shivering, and increased thirst. Ruffled feathers, anemia, and pale combs can be noticed as well, and inappetence can lead to reduced weight. Young birds are affected more severely than older ones. During the initial stages of the disease, there is usually a green or yellow diarrhea with increased urates. The course of the disease is 1–2 wk. Mild strains are common. However, in many tick-infested geographic areas, morbidity can approach 100% and mortality may be 33%–77%. Egg production in layers or breeders may be reduced by 5%–10%, with a higher number of small eggs.

Lesions: The spleen is enlarged, with petechial or ecchymotic hemorrhages, appearing dark or mottled. However, a contrasting situation may be seen in Mongolian pheasants, in which the spleen is reported to be small and pale. Occasionally, the liver may be swollen and contain focal areas of necrosis. Kidneys may be enlarged and pale. A green, catarrhal enteritis is common.

Diagnosis: Diagnosis depends on demonstration of *Borrelia* in the blood, either as actively motile during darkfield microscopy, as stained spirochetes in Giemsa-stained blood smears, or by PCR. In young birds, the *Borrelia* may reach vast numbers per oil-immersion field and persist for several days. Older birds usually have

low numbers of *Borrelia* that are detected only with difficulty, or not at all, and that persist for only 1–2 days. Increased numbers of immature RBCs are noticed due to the anemia. Silver staining can be used to demonstrate the bacteria in tissues.

Agar-gel diffusion and various serologic tests have been described but are of questionable value because of the diverse serotypes that exist in some localities. Specific agglutinins clump the spirochetes in successively larger clumps during the terminal stages of the disease. Agglutination lysis then begins to disintegrate these clumps, and spirochetal degradation products are liberated, which may result in pyrexia. Death occurs most often 1–3 days after *Borrelia* disappear from the bloodstream. Spirochetal antibodies are readily detected in yolks of eggs laid by infected hens.

Treatment and Control: Several antibacterial agents are effective. The most widely used are penicillin derivatives, but streptomycins, tetracyclines, and tylosin are also effective. The antibiotics can be completely effective if begun when the number of spirochetes per oil-immersion field is low or moderate; however, if large numbers of spirochetes are present in the

bloodstream, the sudden liberation of large quantities of spirochetal degradation products can result in higher mortality than with no treatment.

Control must be directed against the biologic vector. *Argas* ticks are notable for their long lifespan, ability to survive for extended periods without a blood meal, efficiency in transmitting the spirochete, and ability to remain securely hidden in cracks and crevices often beyond the effective reach of pesticides. Accordingly, control is difficult. A combination of tick eradication and immunization is the most effective means of control.

Immunization can be highly successful and, next to eradication of the biologic vector, is the preferred method of control. Bacterins prepared from local strains of *Borrelia* have been used with success. Vaccines may be prepared from formalin- or phenol-inactivated material from lysates of blood, tissues, embryos, or eggs infected with *B. anserina*, and may be lyophilized or liquid. Whole-egg propagated bacterins are usually given in one or two IM injections. Little if any cross-protection is afforded to different serotypes. Birds normally have protective immunity after recovering from natural infection.

COLIBACILLOSIS

(Colisepticemia, *Escherichia coli* infection)

Colibacillosis occurs as an acute fatal septicemia or subacute pericarditis, airsacculitis, salpingitis, and peritonitis. It is a common disease of economic importance in poultry and is seen worldwide.

Etiology and Pathogenesis: *Escherichia coli* is a gram-negative, rod-shaped bacterium normally found in the intestine of poultry and most other animals. Although most serotypes are nonpathogenic, a limited number produce extraintestinal infections. Avian pathogenic *E. coli* (APEC) strains are commonly of the O1, O2, and O78 serogroups, but many others have also been associated with cellulitis and colibacillosis. There is considerable diversity of serogroups among clinical isolates, with a high percentage of APEC isolates being untypeable. Therefore, no single *E. coli* serogroup used as a bacterin can provide

full protection against all of the serogroups that cause infections. Virulence factors include possession of large virulence plasmids and the abilities to resist phagocytosis and serum killing, acquire iron in low iron conditions, and adhere to host structures. APEC are generally nontoxicogenic and poorly invasive.

Large numbers of *E. coli* are maintained in the poultry house environment through fecal contamination. Initial exposure to APEC may occur in the hatchery from infected or contaminated eggs. Although most *E. coli* isolated from colibacillosis are well equipped with virulence factors that distinguish them from fecal commensal strains, systemic infection often involves predisposing environmental factors or infectious causes. Thus, mycoplasmosis, infectious bronchitis, Newcastle disease, hemorrhagic enteritis, and turkey bordetellosis, or exposure to

poor air quality and other environmental stresses, may precede colibacillosis.

Systemic infection occurs when large numbers of APEC gain access to the bloodstream from the respiratory tract or intestine. Bacteremia progresses to septicemia and death, or the infection extends to serosal surfaces, pericardium, joints, and other organs.

Clinical Findings and Lesions: Signs are nonspecific and vary with age, organs involved, and concurrent disease. Young birds dying of acute septicemia have few lesions except for an enlarged, hyperemic liver and spleen with increased fluid in body cavities. Birds that survive septicemia develop subacute fibrinopurulent airsacculitis, pericarditis, perihepatitis, and lymphocytic depletion of the bursa and thymus (unusually pathogenic salmonellae produce similar lesions in chicks). Although airsacculitis is a classic lesion of colibacillosis, it is unclear whether it results from primary respiratory exposure or from extension of serositis. Sporadic lesions include pneumonia, arthritis, osteomyelitis, peritonitis, and salpingitis.

Diagnosis: Unlike pathogenic *E coli* associated with illnesses in other animal species, avian isolates are generally nonhemolytic on sheep (5%) blood agar. Isolation of a pure culture of *E coli* from

heart blood, liver, or typical visceral lesions in a fresh carcass indicates primary or secondary colibacillosis. Consideration should be given to predisposing infections and environmental factors. Pathogenicity of isolates is established using multiplex PCR panels for plasmid-mediated virulence genes or when parenteral inoculation of young chicks or poult results in fatal septicemia or typical lesions within 3 days. Pathogenicity can also be detected by inoculation of the allantoic sac of 12-day-old chicken embryos. Resulting gross lesions include cranial and skin hemorrhages in addition to encephalomalacia in embryos inoculated with virulent isolates.

Treatment and Control: Treatment strategies include attempts to control predisposing infections or environmental factors and early use of antibacterials indicated by susceptibility tests. Most isolates are resistant to tetracyclines, streptomycin, and sulfa drugs, although therapeutic success can sometimes be achieved with tetracycline. In fact, 90% of clinical isolates are resistant to tetracycline, with 60% of isolates resistant to five or more antibiotics. Fluoroquinolone use is now banned in many countries, including the USA. Commercial bacterins administered to breeder hens or chicks have provided some protection against homologous *E coli* serogroups.

DUCK VIRAL HEPATITIS

Duck viral hepatitis is an acute, highly contagious, viral disease of young ducklings characterized by a short incubation period, sudden onset, high mortality, and characteristic liver lesions. The disease is of economic importance in all duck-raising areas of the world. Three distinct types of duck hepatitis virus (DHV) have been isolated from diseased ducklings. A natural outbreak of DHV Type I has been reported in mallard ducklings; experimental DHV Type I infections have been produced in goslings, turkey poults, young pheasants, quail, and guinea fowl. In Muscovy ducks, DHV Type 1 has been reported to cause pancreatitis and encephalitis. The viruses that cause hepatitis in ducklings should not

be confused with duck hepatitis B virus, a hepadnavirus infection of older ducks.

Etiology: The originally described, most widespread, and most virulent DHV Type I has been renamed duck hepatitis A virus type 1 (DHAV-1) and is now classified in the genus *Avihepatovirus* in the Picornaviridae family. It is readily propagated in chicken and duck embryos. Two new geno/serotypes, DHAV-2 and DHAV-3, have been identified in China, Taiwan, and Korea. They do not produce hemagglutinins. Field experience with DHAV-1 indicates that egg transmission does not occur. The disease can be transmitted experimentally by parenteral or oral administration of infected tissues.

Viruses that differ from classic DHAV-1 have been recognized as causes of hepatitis in ducklings. DHV Type II, now classified as duck astrovirus type 1 (DASTV-1), is difficult to propagate under laboratory conditions; DHV Type III is also now classified as an astrovirus (DASTV-2) and can be propagated in duck (but not chicken) embryos. Distinct serologic variants of DHAV-1, named DHV Type Ia and N-DHV, have also been described.

Clinical Findings: The incubation period for DHAV-1 is 18–48 hr. Affected ducklings become lethargic, lose balance, paddle spasmodically, and die within minutes, typically with opisthotonos. Although adults may become infected, clinical signs have not been seen in ducks >7 wk old. Mortality may be as high as 95% in ducklings. Practically all deaths occur within 1 wk after onset of signs.

The clinical course of DASTV-1 infection is similar to that of DHAV-1 and can be seen in ducklings immune to DHAV-1 infection. DASTV-2 infections are seen in ducklings despite immunity to DHAV-1. The clinical course of DASTV-2 infection is less severe, and mortality is rarely >30%.

Lesions: The lesions caused by all three types of DHV are similar. The liver is enlarged and covered with hemorrhagic foci up to 1 cm in diameter. The spleen may be enlarged and mottled. Kidneys may be swollen and renal blood vessels congested.

Diagnosis: A presumptive diagnosis can be based on the history and lesions. Sudden onset, rapid spread, and short course, together with characteristic liver lesions, are highly suggestive of duck-viral hepatitis. DHAV-1 may be isolated in duck embryos, day-old ducklings, and duck-embryo liver cell cultures, or less easily in chicken

embryos. The virus can be identified by neutralization with specific antisera or by inoculation into both susceptible and immune ducklings. DHAV-1 can also be identified by reverse transcriptase PCR. DASTV-1 and DASTV-2 are not neutralized by classic DHAV-1 antiserum.

Prevention and Treatment: Prevention is by strict isolation, particularly during the first 5 wk of age. Contact with wild waterfowl should be avoided. Rats have been reported as a reservoir host of the virus; therefore, pest control is indicated.

Immunization of breeder ducks with modified-live virus vaccines, using DHAV-1, DASTV-1, and DASTV-2, provides parenteral immunity that effectively prevents high losses in young ducklings. The DHAV-1 vaccine is administered SC in the neck to breeder ducks at 16, 20, and 24 wk of age and every 12 wk thereafter throughout the laying period. Three immunizations are advisable for passive protection of ducklings.

An inactivated DHAV-1 vaccine for use in breeder ducks that have been previously primed with live DHAV-1 has been described. A single dose of the inactivated vaccine, given IM before the birds come into lay, provides passive immunity for a complete laying cycle to progeny ducklings.

The chick-embryo origin, modified-live DHAV-1 vaccine also can be used for early vaccination of ducklings susceptible to DHAV-1 (progeny of nonimmune breeders). This vaccine is administered SC or by foot web stab in a single dose to day-old ducklings. Vaccinated ducklings rapidly develop an active immunity within 3–4 days.

Antibody against DHAV-1, prepared from the eggs of hyperimmunized chickens and administered SC in the neck at the time of initial loss, is an effective flock treatment.

ENTEROCOCCOSIS

Enterococcosis has been reported in a variety of avian species worldwide.

Enterococcus spp are normal microflora found in the intestinal tract of poultry and other bird species; infections are usually secondary to another disease. *Enterococcus* infections can result in either an acute or subacute/chronic form.

Etiology and Epidemiology: Enterococci are nonmotile, gram-positive, catalase-negative coccoid bacteria that appear singly, in pairs, or in short chains on stained smears. *Enterococcus* spp isolated from birds with clinical disease include *E. avium*, *E. durans*, *E. faecalis*, *E. faecium*, and *E. hirae*. *E. faecalis* affects birds of all

ages, but infection is especially devastating for embryos and young chicks. *E. cecorum* has been associated with arthritis in broiler chickens.

Transmission is via the oral and/or aerosol routes as well as from skin wounds. Infection may result in septicemia. Endocarditis can occur when the infection progresses to a subacute/chronic stage. Brain necrosis and encephalomalacia in young chickens have been reported in enterococcosis. Although enterococcosis has been reported in poultry species, it should also be noted that some strains of *Enterococcus* have a beneficial effect on growth and feed efficiency and are used as probiotics.

Clinical Findings: In the acute form of enterococcosis, clinical signs are related to septicemia and include depression, lethargy, ruffled feathers, diarrhea, and a decrease in egg production. In the subacute/chronic form, depression, lameness, and head tremors may be noted. If untreated, most affected birds die. Egg transmission or fecal contamination of hatching eggs can often lead to late embryo mortality, and an increased number of hatchlings are unable to "pip" through the shell at hatch.

Lesions: Acute enterococcosis lesions include splenomegaly, hepatomegaly, enlarged kidneys, and congestion of subcutaneous tissue. Multifocal, whitish-tan areas of necrosis may be observed on the liver and spleen. Omphalitis or enlarged yolk sacs may be seen in infected chicks or poults. In the subacute/chronic form, lesions include pericarditis, perihepatitis, airsacculitis, arthritis and/or tenosynovitis, osteomyelitis, myocarditis, and valvular endocarditis. An enlarged, flaccid heart with pale to hemorrhagic areas in the myocar-

dium has also been reported along with infarcts throughout the internal organs. Focal granulomas can be found in many tissues as a result of septic emboli. Gram-positive bacterial colonies are readily seen in thrombosed vessels and within areas of necrosis.

Diagnosis: History, clinical signs, lesions, and demonstration of enterococci in blood or on impression smears are suggestive of enterococcosis. Isolation of *Enterococcus* spp from lesions will confirm the diagnosis. Enterococci are easily isolated on blood agar. Differential diagnoses includes bacterial septicemic diseases such as staphylococcosis, streptococcosis, colibacillosis, pasteurellosis, and erysipelas.

Treatment and Prevention: Antibiotics, including penicillin, erythromycin, novobiocin, oxytetracycline, chlortetracycline, or tetracycline, have been used to treat acute and subacute infections. Clinically affected birds respond well early in the course of the disease, but treatment efficacy decreases as the disease progresses. Antimicrobial susceptibility testing should be performed to ensure that the most efficacious antibiotic is used.

Prevention and control require preventing immunosuppressive diseases and conditions, because enterococcosis often occurs secondary to another disease. In addition, ensuring proper cleaning and disinfection of the facilities can reduce environmental sources.

Zoonotic Risk: A high percentage of ready-to-eat poultry products are contaminated with *Enterococcus* spp; however, food poisoning in people has not been reported.

ERYSIPELAS

Erysipelas is a bacterial disease caused by infection with *Erysipelothrix rhusiopathiae*. The disease is most often seen as septicemia, but urticarial and endocardial forms exist. *E. rhusiopathiae* infects a wide range of both avian and mammalian hosts. The disease has been reported in domestic fowl, feral avian species, and captive wild birds and mammals. Infection in reptiles and amphibians has been reported. The organism

has also been isolated from the surface slime on fish (without causing disease), which may serve as a source of infection for other species. From an economic standpoint, turkeys are the most important poultry species affected, but serious outbreaks have occurred in chickens, ducks, and geese. Among affected mammals, swine are the most economically important species, but *E. rhusiopathiae* infection is also a cause of

polyarthritis in lambs. (See also *ERYSIPELOTHRIX RHUSIOPATHIAE* INFECTION, p 625.)

Erysipelas in poultry is seen worldwide and, although considered a sporadic disease, endemic areas exist.

Etiology: *E rhusiopathiae* is a facultative, anaerobic bacterium. Two additional genomic species have been described: *E tonsillarum*, and most recently *E inopinata*, but neither is considered pathogenic for poultry. Morphologically, *E tonsillarum* and *E inopinata* cannot be distinguished from *E rhusiopathiae*. *E rhusiopathiae* stains gram-positive but tends to decolorize, particularly in older cultures. The organism is small, non-acid fast, nonmotile, does not form spores, and produces no known toxins. There is no flagellum, but a capsule has been demonstrated. The cellular morphology of *E rhusiopathiae* is variable. The presence of virulence factors such as neuraminidase play a role in bacterial attachment and invasion of host cells. Cells freshly isolated from tissues during acute infection or from smooth colonies are straight or slightly curved small rods that may occur in short chains. Cells from older cultures or rough colonies tend to become filamentous and may be confused with mycelia. The filamentous form occurs more frequently after repeated passages on artificial media.

E rhusiopathiae has three colony types and grows readily on ordinary culture media containing the blood or sera of various animals. Growth is enhanced by reducing the oxygen content or increasing the carbon dioxide level to 5%–10%. Optimal incubation temperature is 35°–37°C, and the optimal pH range is 7.4–7.8.

The organism is not readily destroyed by the usual laboratory disinfectants. It is quite resistant to dessication and can survive smoking and pickling processes. It may survive in litter or soil for various lengths of time. Infected carriers may shed the organism, seeding the environment and making disinfection of premises difficult. It is inactivated by a 1:1,000 concentration of bichloride of mercury, 0.5% sodium hydroxide solution, 3.5% liquid cresol, 5% solution of phenol, quaternary ammonium, chlorine, or 0.5% formalin as long as it is not in organic matter.

Although 26 different serotypes of *E rhusiopathiae* were described based on an agar gel diffusion test, some of these serotypes have been assigned to *E tonsillarum* after its confirmation as a separate species. *E rhusiopathiae* serotypes 1, 2, and 5 have been most frequently isolated from poultry.

Epidemiology: Erysipelas occurs sporadically in poultry of all ages. It is ubiquitous in nature and found where nitrogenous substances decompose. Turkeys are susceptible regardless of sex or age, although under field conditions it is more common in older birds. Recent evidence indicates there may be a genetically related resistance in turkeys. The incidence in males is reported to be higher, but this is not supported by experimental data. Erysipelas may affect the fertility of males and may contribute to downgrading and processing losses. Infection results from entrance of the organisms through breaks in the skin, through the mucous membranes such as during artificial insemination, by ingestion of contaminated foodstuffs (particularly cannibalism of infected carcasses), and possibly by mechanical transmission via biting insects. The poultry red mite (see p 2877) can harbor the organism and may serve as a mechanical vector. Fighting and cannibalism increase losses.

The organism is shed in feces from infected animals and contaminates the soil, in which it may survive for long periods depending on temperature and pH. Poultry, as well as other animals, may be carriers and shed the organism without showing clinical signs of disease. Carriers can shed from feces, urine, saliva, and nasal secretions. Transmission into poultry houses via rodents can occur.

In nonvaccinated flocks, morbidity and mortality rates may reach 40%–50%, but mortality is usually <15%. In vaccinated flocks, some birds may be depressed for a short period and recover. Mortality in vaccinated and nonvaccinated poultry is influenced by the virulence of the organism.

No correlation has been shown to exist between the serotype, chemical structure, or biochemical pattern and the manifestation of the septicemic, urticarial, or endocardial forms of erysipelas.

Clinical Findings: Erysipelas is primarily an acute infection that results in sudden death. In an affected flock, a few birds may be depressed but easily aroused; within 24 hr, a few birds will be dead. Just before death, some birds may be very droopy, with an unsteady gait. Chronic clinical disease in a flock is not usual but does occur; birds may have cutaneous lesions and swollen hocks. Turkeys with vegetative endocarditis usually do not have clinical signs and may die suddenly. Erysipelas should be suspected in flocks that have been

artificially inseminated 4–5 days before an episode of death without clinical signs. Rainy, cold weather coinciding with the onset of sexual maturity increases risk of clinical disease. Clinical signs in chickens include general weakness, depression, diarrhea, and sudden death. Most sick birds die. In laying hens, egg production may drop markedly. Decreased egg production and conjunctival edema can be seen in organic, cage-free flocks.

Lesions: At necropsy, a generalized darkening of the skin or various sized areas of diffuse darkening is common. The liver and spleen are usually enlarged and friable and may be mottled. Other gross lesions such as peritonitis, pericarditis, petechiation of the heart, catarrhal exudate in the GI tract, and degeneration of fat associated with the thigh and heart may be noted. Vascular damage and fibrin thrombi are common findings on microscopic examination.

Diagnosis: A presumptive diagnosis can be based on an impression smear of the liver or spleen or on a smear of cardiac blood or bone marrow that shows gram-positive, slender, pleomorphic rods. Bone marrow is the tissue of choice in partially decomposed specimens. Isolation and identification of *E. rhusiopathiae* is necessary for definitive diagnosis. Identification can be made by fluorescent antibody staining and PCR. PCR can distinguish *E. rhusiopathiae* from *E. tonsillarum*. A mouse ear scarification model has been described and is particularly helpful for mixed cultures. An indirect ELISA is available, but virtually all poultry are exposed, with antibody levels increasing with age. Caution must be used in attempting reisolation, because the organism produces pinpoint colonies that may be easily overlooked or masked by faster-growing bacteria. Highly selective media are available for reisolation.

Infections with *Escherichia coli* or *Pasteurella multocida*, as well as salmonellosis and peracute Newcastle disease, may be confused with the septicemic form of erysipelas. Urticaria and endocarditis may be caused by other miscellaneous bacterial or fungal pathogens. Noninfectious differential diagnoses include poisoning, stampede injuries, or predators.

Treatment, Control, and Prevention:

The antibiotic of choice is a rapid-acting penicillin such as potassium or sodium penicillin. As soon as a presumptive

diagnosis is made, penicillin should be administered IM at 22,000 U/kg body wt, simultaneously with a full dose of erysipelas bacterin. Injectable penicillin is warranted for an acute outbreak but may be an extra-label use. In situations in which it is impractical to handle every bird, administration of penicillin in the drinking water at 395,000 U/L for 4–5 days reduces losses. Sulfonamides and oral oxytetracycline are not effective; broad-spectrum antibiotics, eg, erythromycin, are effective. Antibiotic in feed or water treats only those in the flock that are still eating and drinking normally and may not have dramatic results. Recovered birds have a high degree of resistance. Vaccination with a bacterin helps protect those birds in the flock not yet infected. However, bacterin-derived immunity is not long-lasting and may require two or more injections at intervals of 2–4 wk. Antibiotic therapy or vaccination does not eliminate the carrier state. Antibiotic resistance to tetracycline has been reported.

Vaccination will control erysipelas. Both inactivated and live vaccines are available for use in turkeys; only vaccines approved for use in turkeys should be used. The use of bacterins in flocks used for meat is useful but labor intensive. For breeders, the bacterin should be given every 4 wk before onset of egg production. The use of live vaccines administered in the drinking water does not require handling each bird and, therefore, is less stressful. Live vaccines require two doses at intervals of 2–3 wk. Commercially available swine erysipelas vaccine can be used in layers and is given at up to two times the recommended dose for swine via injection. It does not interfere with egg production. Although the swine vaccine is safe, no challenge studies have been done.

There are no specific husbandry recommendations other than sound management practices for the control of erysipelas in poultry, particularly in endemic areas. After an outbreak, equipment should be thoroughly disinfected and dead birds removed from the premises.

Zoonotic Risks: *E. rhusiopathiae* can infect people and causes three different syndromes: erysipeloid, a generalized cutaneous form, and a septicemic form with endocarditis. The organism usually enters through cuts in the skin, and those at risk include people who handle infected tissues, such as veterinarians, butchers, and fish handlers. There have been no reports of people becoming infected through the oral route.

FATTY LIVER HEMORRHAGIC SYNDROME

Fatty liver hemorrhagic syndrome (FLHS) was first described in the 1950s as excessive fat in the liver of prolific laying hens, associated with varying degrees of hemorrhage. The condition is almost universally confined to caged birds fed high-energy diets and is most often seen in white-egg layers in warm, summer months. The liver is usually enlarged, putty colored, and very friable, showing varying degrees of hemorrhage. The abdominal cavity often contains large amounts of oily, unsaturated fat. Affected birds often have pale combs, likely as a consequence of reduced egg production. The ovary is usually active, at least in the early stages of FLHS, and the metabolic and physical stress associated with oviposition may be factors that induce the final fatal hemorrhage.

Because FLHS seems to occur only when birds are in a positive energy balance, body weight monitoring is a good diagnostic tool, as is knowledge of daily feed intake and environmental temperature. Through force-feeding techniques, it has been shown that FLHS is caused by a surfeit of energy rather than an excess of any particular nutrients such as fat or carbohydrate. The condition can be induced experimentally in layers and even male birds by administration of estrogen. This supports the concept that FLHS occurs more frequently in high-producing birds that presumably are producing more estrogen from very active ovaries. Injecting immature pullets with testosterone also causes increased feed intake and liver fat accumulation, although without any major incidence of fatty liver.

FLHS is easy to recognize at necropsy because of the liver hemorrhage and the fact that the liver is enlarged and engorged with fat. This makes the liver friable, and it is difficult to remove each lobe in one piece. The pale yellow color of the liver, while characteristic, is not always specific to FLHS. Normal layers that are fed appreciable quantities of yellow corn or high levels of xanthophyll pigments will also have a yellow-colored liver but without associated hemorrhages. A number of specific diet ingredients can induce liver hemorrhage but without concomitant accumulation of excess fat. Likewise, feeding rancid fat can cause liver hemorrhage, again without fat accumulation. In birds with FLHS, the liver dry matter is characteristically at least 40% fat. The degree of FLHS can be described as a poultry liver hemorrhage score, which is

usually based on a scale of 1–5, in which 1 = no hemorrhage; 2 = 1–5 hemorrhages; 3 = 6–15 hemorrhages; 4 = 16–25 hemorrhages; and 5 = >25 hemorrhages, as well as a massive, usually fatal, hemorrhage. There is some evidence that fatty liver disorder also impairs calcium metabolism in the bird, and hence skeletal integrity and eggshell quality. Layers with FLHS have increased blood levels of estrogen, osteocalcin, and leptin-like protein. There seems to be concomitant upregulation in bone turnover, which is a very significant occurrence for a laying hen that already relies on significant daily flux of calcium in and out of the skeleton.

Attempts have been made to prevent or treat the condition through dietary modification. Substituting carbohydrate with supplemental fat, while not increasing the energy content of the diet, seems to be beneficial. Presumably such modification means that the liver needs to synthesize less fat for yolk. Replacement of corn with other cereals, such as wheat and barley, is often beneficial. However, this substitution may involve reducing the dietary energy level or necessitate using additional fat to maintain isoenergetic conditions, two factors known to influence FLHS. FLHS has reportedly been reduced through the use of various byproduct feeds such as distiller's grains, fish meal, and alfalfa meal. Although such mode of action is unclear, unintentional supplementation of selenium may be involved. There are reports of layers having greater incidence of fatty liver when fed chelated trace minerals versus conventional inorganic minerals. However, the use of organic minerals in layer diets is increasing, and FLHS is not usually reported. There are also reports of association with *Mycoplasma* infection.

FLHS is best prevented by not allowing an excessive positive energy balance in older birds. Body weight can be monitored and, when potential problems are seen, remedial action taken to limit energy intake through the use of lower energy diets and/or change in feed management. A wide energy:protein ratio in the diet will aggravate FLHS. When a farm has a history of FLHS, the diet should contain at least 0.3 ppm selenium, ideally as organic selenium, up to 100 IU vitamin E/kg diet, and appropriate levels of an antioxidant such as ethoxyquin. These various additives collectively help to limit the occurrence of tissue rancidity, and hence hemorrhage of the excess fat in the liver.

SUDDEN DEATH SYNDROME OF BROILER CHICKENS

(Flip-over disease, Acute death syndrome, Dead in good condition)

A syndrome of sudden death has been reported in most areas of the world that raise broilers intensively. Young, healthy, fast-growing broiler chickens die suddenly with a short, terminal, wing-beating convulsion. Many affected broilers just “flip over” and die on their backs; 60%–80% are males. The condition is uncommon or unrecognized when low-density feed is used.

Etiology and Epidemiology: The cause is unknown, but it is thought to be a metabolic disease related to carbohydrate metabolism, lactic acidosis, loss of cell membrane integrity, and intracellular electrolyte imbalance. Recent studies link this disease to cardiac arrhythmias. The modern broiler, which has been selected for growth rate and feed conversion efficiency, has a predisposition to cardiac arrhythmias. One study found the prevalence of arrhythmias to be much higher in broilers (27%) than leghorns (1%), but it is not clear whether this predisposition is dietary or genetic. Stress is the most likely trigger of cardiac arrhythmias in broilers, which predisposes the bird to death from ventricular fibrillation. The prevalence in a rapidly growing healthy broiler flock is typically 0.5%–4%.

Clinical Findings: Broilers show no premonitory signs. They appear healthy and may be feeding, sparring, walking, or resting, but suddenly extend their necks, gasp or squawk, and die rapidly with a short period of wing beating and leg movement, during which they frequently flip onto their backs. They also may be found dead on their sides or breasts.

Sudden death syndrome may occur as early as day 3 and may continue until 10–12 wk in roaster flocks. Mortality usually peaks between days 12 and 28, although it may peak as early as day 9. If growth is restricted early, it may peak only after day 28. Mortality of 0.25%–0.5% per day can occur for 1–3 days.

Lesions: There are no specific gross lesions. Recent studies indicate that affected birds have characteristic microscopic lesions in cardiomyocytes and subendocardial Purkinje cells, and this may

help in diagnosis. Dead birds are well fleshed, have an empty or partially filled crop, and feed in the gizzard. The abdomen is distended because the bird is fat and the intestines are filled with ingesta, indicating peracute death. The muscles are mottled red and white as a result of focal congestion, and the organs are moderately to severely congested. There may be small hemorrhages in the liver and kidney. Although the ventricles of the heart are contracted, there is no sign of hypertrophy, and the atria are dilated and blood filled. The lungs are congested and frequently edematous; however, pulmonary edema increases with time after death and is not prominent in broilers that are examined within a few minutes of death. The gallbladder may be small or empty, because feed intake is normal up until the time of death.

Diagnosis: Sudden death syndrome should be suspected in well grown and otherwise healthy-looking broilers found dead on their backs, because that position is rare in death from other causes except cardiac tamponade, asphyxia, and ascites syndrome (see p 2871). The syndrome is also the likely cause when dead birds that are otherwise in good condition are found lying on their sides or breasts randomly throughout the pen. Diagnosis is supported by necropsy findings if there is a lack of obvious pathology (ie, a digestive tract filled with ingesta, contracted ventricles, dilated and blood-filled atria, lung congestion, and edema). The presence of characteristic microscopic lesions in cardiomyocytes and subendocardial Purkinje cells is helpful in confirming the diagnosis. Affected cells have vacuolated sarcoplasm, cytoplasmic eosinophilia, and nuclear pyknosis.

The condition called sudden death syndrome in Australia in broiler breeders coming into production is a different disease; it is reported to be caused by potassium deficiency. Similar mortality caused by a combination of high environmental temperature and hypophosphatemia or by acute hypocalcemia has been reported in North America.

Sudden death in turkeys can be caused by choke, aortic rupture (see p 2787), focal

(obstructive) granulomatous pneumonia, or by hypertrophic cardiomyopathy (see p 2790) with lung congestion and edema, splenomegaly, and perirenal hemorrhage (see p 2789).

Prevention and Control: The incidence of sudden death syndrome can be mini-

mized by slowing the growth rate of broilers, particularly during the first 3 wk of life. Growth rate can be moderated by controlling nutrient intake. This can be accomplished by reducing the number of hours of light per day, reducing the energy and protein level in the diet, or limiting the amount of feed provided.

FOWL CHOLERA

Fowl cholera is a contagious, bacterial disease that affects domestic and wild birds worldwide. It usually occurs as a septicemia of sudden onset with high morbidity and mortality, but chronic and asymptomatic infections also occur.

Etiology and Transmission: *Pasteurella multocida*, the causal agent, is a small, gram-negative, nonmotile rod with a capsule that may exhibit pleomorphism after repeated subculture. *P. multocida* is considered a single species although it includes three subspecies: *multocida*, *septica*, and *gallicida*. Subspecies *multocida* is the most common cause of disease, but *septica* and *gallicida* may also cause cholera-like disease.

In freshly isolated cultures or in tissues, the bacteria have a bipolar appearance when stained with Wright's stain. Although *P. multocida* may infect a wide variety of animals, strains isolated from nonavian hosts generally do not produce fowl cholera. Strains that cause fowl cholera represent a number of immunotypes (or serotypes), which complicates efforts at widespread prevention using bacterins. The organism is susceptible to ordinary disinfectants, sunlight, drying, and heat. Turkeys and waterfowl are more susceptible than chickens, older chickens are more susceptible than young ones, and some breeds of chickens are more susceptible than others.

Chronically infected birds and asymptomatic carriers are considered to be major sources of infection. Wild birds may introduce the organism into a poultry flock, but mammals (including rodents, pigs, dogs, and cats) may also carry the infection. However, the role of these as a reservoir has not been thoroughly investigated. Dissemination of *P. multocida* within a flock and between houses is primarily by excretions from the mouth, nose, and conjunctiva of

diseased birds that contaminate their environment. In addition, *P. multocida* survives long enough to be spread by contaminated crates, feed bags, shoes, and other equipment. The infection does not seem to be egg-transmitted.

Clinical Findings: Clinical findings vary greatly depending on the course of disease. In acute fowl cholera, finding a large number of dead birds without previous signs is usually the first indication of disease. Mortality often increases rapidly. In more protracted cases, depression, anorexia, mucoid discharge from the mouth, ruffled feathers, diarrhea, and increased respiratory rate are usually seen. Pneumonia is particularly common in turkeys.

In chronic fowl cholera, signs and lesions are generally related to localized infections of the sternal bursae, wattles, joints, tendon sheaths, and footpads, which often are swollen because of accumulated fibrinous-suppurative exudate. There may be exudative conjunctivitis and pharyngitis. Torticollis may result when the meninges, middle ear, or cranial bones are infected.

Lesions: Lesions observed in peracute and acute forms of the disease are primarily vascular disturbances. These include general passive hyperemia and congestion throughout the carcass, accompanied by enlargement of the liver and spleen. Petechial and ecchymotic hemorrhages are common, particularly in subepicardial and subserosal locations. Increased amounts of peritoneal and pericardial fluids are frequently seen. In addition, acute oophoritis with hyperemic follicles may be observed. In subacute cases, multiple, small, necrotic foci may be disseminated throughout the liver and spleen.

In chronic forms of fowl cholera, suppurative lesions may be widely

Swollen wattles in a broiler breeder male as the result of a chronic fowl cholera infection. Courtesy of Dr. Jean Sander.

distributed, often involving the respiratory tract, the conjunctiva, and adjacent tissues of the head. Caseous arthritis and productive inflammation of the peritoneal cavity and the oviduct are common in chronic infections. A fibrinonecrotic dermatitis that includes caudal parts of the dorsum, abdomen, and breast and involves the cutis, subcutis, and underlying muscle has been observed in turkeys and broilers. Sequestered necrotic lung lesions in poultry should always raise suspicion of cholera.

Diagnosis: Although the history, signs, and lesions may aid diagnosis, *P. multocida* should be isolated, characterized, and identified for confirmation. Primary isolation can be accomplished using media such as blood agar, dextrose starch agar, or trypticase soy agar. Isolation may be improved by the addition of 5% heat-inactivated serum. *P. multocida* can be readily isolated from viscera of birds dying from peracute/acute fowl cholera, whereas isolation from

suppurative lesions of chronic cholera may be more difficult. At necropsy, bipolar microorganisms may be demonstrated by the use of Wright's or Giemsa stain of impression smears obtained from the liver in the case of acute cholera. In addition, immunofluorescent microscopy and in situ hybridization have been used to identify *P. multocida* in infected tissues and exudates.

PCR has been used for the detection of *P. multocida* in pure and mixed cultures and clinical samples. This method may help identify carrier animals within flocks. However, the specificity and sensitivity of the PCR must be improved. *P. multocida* can be subgrouped by capsule serogroup antigens into five capsular types (A, B, D, E, and F) and into 16 somatic serotypes. Somatic serotyping is important to choose the right bacterins for prevention. However, conventional serotyping suffers from problems with reproducibility and reliability, and the methods are quite laborious. Recently, a multiplex PCR has been developed that can differentiate between different somatic serotypes. This will be of great value as a diagnostic tool and enable more efficient vaccine development in the future.

Serologic testing can be done by rapid whole blood agglutination, serum plate agglutination, agar diffusion tests, and ELISA. Serology may be used to evaluate vaccine responses but has very limited value for diagnostic purposes.

Several bacterial infections may be confused with fowl cholera based solely on the gross lesions. *Escherichia coli*, *Salmonella enterica*, *Ornithobacterium rhinotracheale*, gram-positive cocci, and *Erysipelothrix rhusiopathiae* (erysipelas) may all produce lesions indistinguishable from those caused by *P. multocida*.

Prevention: Good management practices, including a high level of biosecurity, are essential to prevention. Rodents, wild birds, pets, and other animals that may be carriers of *P. multocida* must be excluded from poultry houses. Adjuvant bacterins are widely used and generally effective; autogenous bacterins are recommended when polyvalent bacterins are found to be ineffective. Thus, it is important to know the most prevalent serotypes within an area to choose the right bacterins. Attenuated live vaccines are available for administration in drinking water to turkeys and by wing-web inoculation to chickens. These live vaccines can effectively induce immunity against different serotypes of *P. multocida*. They are recommended for use in healthy flocks only.

Treatment: A number of drugs will lower mortality from fowl cholera; however, deaths may resume when treatment is discontinued, showing that treatment does not eliminate *P. multocida* from a flock. Eradication of infection requires depopulation and cleaning and disinfection of buildings and equipment. The premise should then be kept free of poultry for a few weeks.

Sulfonamides and antibiotics are commonly used; early treatment and adequate dosages are important. Sensitivity testing often aids in drug selection and is important because of the emergence of multiresistant strains. Sulfaquinoxaline sodium in feed or water usually controls

mortality, as do sulfamethazine and sulfadimethoxine. Sulfas should be used with caution in breeders because of potential toxicity. High levels of tetracycline antibiotics in the feed (0.04%), drinking water, or administered parenterally may be useful. Norfloxacin administered via drinking water is also effective against fowl cholera. However, many countries do not allow the use of quinolones in food-producing animals, including poultry, because of the risk of development of drug resistance. Penicillin is often effective for sulfa-resistant infections. In ducks, a combined injection of streptomycin and dihydrostreptomycin can be effective.

FOWLPOX

FOWLPOX IN CHICKENS AND TURKEYS

Fowlpox is a slow-spreading viral infection of chickens and turkeys characterized by proliferative lesions in the skin that progress to thick scabs (cutaneous form) and by lesions in the upper GI and respiratory tracts (diphtheritic form). Virulent strains may cause lesions in the internal organs (systemic form). Fowlpox is seen worldwide.

Etiology and Epidemiology: The large DNA virus (an avipoxvirus in the Poxviridae family) is resistant and may survive in the environment for extended periods in dried scabs. Photolyase and A-type inclusion body protein genes in the genome of fowlpox virus appear to protect the virus from environmental insults. Field and vaccine strains have only minor differences in their genomic profiles, although the strains can be differentiated to some extent by restriction endonuclease analysis and immunoblotting. Recently, molecular analyses of vaccine and field strains of fowlpox viruses have shown some significant differences. The virus is present in large numbers in the lesions and is usually transmitted by contact through abrasions of the skin. Skin lesions (scabs) shed from recovering birds in poultry houses can become a source of aerosol infection. Mosquitoes and other biting insects may serve as mechanical vectors. Transmission within flocks is rapid when mosquitoes are plentiful. The disease tends

to persist for extended periods in multiple-age poultry complexes because of slow spread of the virus and availability of susceptible birds.

Clinical Findings: The cutaneous form of fowlpox is characterized by nodular lesions on various parts of the unfeathered skin of chickens and on the head and upper neck of turkeys. Generalized lesions of feathered skin may also be seen. In some cases, lesions are limited chiefly to the feet and legs. The lesion is initially a raised, blanched, nodular area that enlarges, becomes yellowish, and progresses to a thick, dark scab. Multiple lesions usually develop and often coalesce. Lesions in various stages of development may be found on the same bird. Localization around the nostrils may cause nasal discharge. Cutaneous lesions on the eyelids may cause complete closure of one or both eyes. Only a few birds develop cutaneous lesions at one time. Lesions are prominent in some birds and may significantly decrease flock performance.

In the diphtheritic form of fowlpox, lesions develop on the mucous membranes of the mouth, esophagus, pharynx, larynx, and trachea (wetpox or fowl diphtheria). Occasionally, lesions are seen almost exclusively in one or more of these sites. Caseous patches firmly adherent to the mucosa of the larynx and mouth or proliferative masses may develop. Mouth lesions interfere with feeding. Tracheal lesions cause difficulty in respiration. Laryngeal and tracheal lesions in chickens must be

Scab-like lesion on the unfeathered portion of the skin due to fowlpox on a turkey.

Courtesy of Dr. Jean Sander.

differentiated from those of infectious laryngotracheitis (*see* p 2912), which is caused by a herpesvirus. In cases of systemic infection caused by virulent fowlpox virus strains, lesions may be seen in internal organs. More than one form of the disease, ie, cutaneous, diphtheritic, and/or systemic, may be seen in a single bird.

Often, the course of the disease in a flock is protracted. Extensive infection in a layer flock results in decreased egg production. Cutaneous infections alone ordinarily cause low or moderate mortality, and these flocks generally return to normal production after recovery. Mortality is usually high in diphtheritic or systemic infections.

Diagnosis: Cutaneous infections usually produce characteristic gross and microscopic lesions. When only small cutaneous lesions are present, it is often difficult to distinguish them from abrasions caused by fighting. Microscopic examination of affected tissues stained with H&E reveals eosinophilic cytoplasmic inclusion bodies. Cytoplasmic inclusions are also detectable by fluorescent antibody and immunohistochemical methods (using antibodies against fowlpox virus antigens). The elementary bodies in the inclusion bodies can be detected in smears from lesions stained by the Gimenez method. Viral particles with typical poxvirus morphology can be demonstrated by negative-staining electron microscopy as well as in ultrathin sections of the lesions. The virus can be isolated by inoculating chorioallantoic membrane of developing chicken embryos, susceptible birds, or cell cultures of avian origin. Chicken embryos (9–12 days old) from an SPF flock are the preferred and convenient host for virus isolation.

The genomic profiles of field isolates and vaccine strains of fowlpox virus can be compared by restriction fragment length polymorphism. This method is useful to compare closely related DNA genomes. However, because of the large size of the genome, minor differences are difficult to detect by this method. Detailed genetic analysis reveals differences between vaccine strains and field strains responsible for outbreaks of fowlpox in previously vaccinated chicken flocks. Whereas vaccine strains of fowlpox virus contain remnants of long terminal repeats of reticuloendotheliosis virus (REV), most field strains contain full-length REV in their genome.

Nucleic acid probes derived from cloned genomic fragments of fowlpox virus can also be used for diagnosis. This procedure is especially useful for differentiation of the diphtheritic form of fowlpox (involving the trachea) from infectious laryngotracheitis.

PCR can be used to amplify genomic DNA sequences of various sizes using specific primers. This procedure is useful when an extremely small amount of viral DNA is present in the sample. PCR has been used effectively to differentiate field and vaccine strains of the virus, whether full-length REV is present in those strains that are associated with outbreaks in vaccinated birds. DNA isolated from the formalin-fixed tissue sections of birds that are histologically positive for fowlpox can be used for PCR amplification of genomic fragments using specific primers. Because most outbreaks of fowlpox in previously vaccinated chickens are caused by strains with a genome that contains full-length REV, use of REV envelope-specific primers to determine the presence of full-length REV is helpful in such cases.

Two monoclonal antibodies that recognize different fowlpox virus antigens have been developed. These monoclonal antibodies are useful for strain differentiation by immunoblotting.

The complete nucleotide sequence of the fowlpox virus genome has been determined. It is useful in comparing the sequences of selected genes of other avian poxviruses.

Prevention and Treatment: Where fowlpox is prevalent, chickens and turkeys should be vaccinated with a live-embryo or cell-culture-propagated virus vaccine. The most widely used vaccines are attenuated fowlpox virus and pigeonpox virus isolates of high immunogenicity and low pathogenicity. In high-risk areas, vaccination with an attenuated vaccine of cell-culture origin in the first few weeks of life and revaccination at 12–16 wk is often sufficient. Health of

birds, extent of exposure, and type of operation determine the timing of vaccinations. Because the infection spreads slowly, vaccination is often useful in limiting spread in affected flocks if administered when <20% of the birds have lesions. Passive immunity may interfere with multiplication of vaccine virus; progeny from recently vaccinated or recently infected flocks should be vaccinated only after passive immunity has declined. Vaccinated birds should be examined 1 wk later for swelling and scab formation ("take") at the site of vaccination. Absence of "take" indicates lack of potency of vaccine, passive or acquired immunity, or improper vaccination. Revaccination with another serial lot of vaccine may be indicated.

Naturally infected or vaccinated birds develop humoral as well as cell-mediated immune responses. Humoral immune responses can be measured by ELISA or virus neutralization tests.

Zoonotic Risk: There is no zoonotic risk associated with fowlpox virus. Avian poxviruses cause a productive infection in avian species but a nonproductive infection in mammalian hosts. Consequently, avianpox viruses have been used as vectors for expression of genes from mammalian pathogens in the development of safe recombinant vaccines.

POX IN OTHER AVIAN SPECIES

Infections with avian poxvirus have been seen in a variety of wild and pet birds. Some isolates are primarily infectious for only the homologous host, whereas others are infectious for one or more additional species. In the absence of genetic information on most of these viruses, classification has usually been based on host pathogenicity or cross-protection studies. The nucleotide sequence of canarypox virus

genome has been determined. Canarypox virus infection is usually severe, and mortality sometimes approaches 100%. Cutaneous lesions may develop, as may systemic infection with cytoplasmic inclusion bodies detected in lesions on histologic examination. A commercial vaccine for canaries is available in the USA. Poxvirus infection in psittacines may also be severe, especially in blue-fronted Amazon parrots. Poxviruses isolated from psittacines appear to be antigenically different from poxviruses of other avian species.

Genomic profiles of canarypox, mynahpox, and quailpox viruses show marked differences from fowlpox virus when their DNA is compared by restriction fragment length polymorphism after restriction endonuclease digestion. Quailpox virus shows marked antigenic differences from fowlpox virus and, although some cross-reacting antigens are present, provides limited or no cross-protection against fowlpox virus. Avianpox virus infection has been considered as a population-limiting factor in endangered Hawaiian forest birds. Avianpox viruses isolated from Hawaiian crows (*Corvus hawaiiensis*), Hawaiian geese (*Branta sandvicensis*), Palila (*Loxioides bailleui*), and Apapane species (*Himatione sanguinea*) are different from each other and from fowlpox virus. Similarly, a poxvirus isolated from an Andean condor (*Vultur gryphus*) at the San Diego Zoo is antigenically, genetically, and biologically different from fowlpox virus. Like fowlpox virus, these viruses appear to be suitable vectors for expression of foreign genes toward development of genetically modified virus vaccines for mammalian species. Several canarypox virus vectored vaccines expressing genes of mammalian pathogens are available commercially.

GOOSE PARVOVIRUS INFECTION

(Derzsy disease, Goose hepatitis, Goose plague)

Goose parvovirus infection is a highly contagious and fatal disease of goslings and Muscovy ducklings, often causing as much as 70%–100% mortality in goslings <4 wk old. Goose parvovirus has been reported from all the major goose-farming countries of Europe and the Far East, where the disease is of serious economic significance.

Muscovy ducks and several hybrid duck breeds are also susceptible to another parvovirus that has been shown to be antigenically related to goose parvovirus. This so-called Muscovy duck parvovirus has been isolated from an outbreak among Muscovy ducks in California. Goose parvovirus has not been detected in the USA.

Etiology: Goose parvovirus is a member of the family Parvoviridae and, based on phylogenetic analysis, has been shown to be related to the dependovirus genus. Apart from the Muscovy duck parvovirus, to which it is closely related, goose parvovirus shows no similarity to the other avian or mammalian parvoviruses. After primary infection, the virus replicates in the intestinal wall and, after a short viremic phase, reaches the heart, liver, and other organs.

Transmission and Epidemiology: The virus is excreted in large amounts in the feces of infected birds, resulting in rapid spread by direct and indirect means.

● Outbreaks are often initiated in susceptible goslings after transmission of the virus via eggs laid by infected breeder geese. Evidence suggests that older, subclinically infected geese may act as carriers. Infected eggs are often the source of the virus when outbreaks of goose parvovirus occur in countries or geographic locations formerly free of the disease. Serologic evidence suggests that the virus is present in several species of wild geese in Europe. No other avian or biologic vectors have been identified.

Clinical Findings: In susceptible goslings and ducklings, clinical signs vary according to the age of the birds. The course of the disease in birds <1 wk old is rapid, with anorexia and death occurring within 2–5 days. Mortality can reach 100% in birds infected in the hatchery. In older birds, the disease follows a more protracted course, characterized by ocular and nasal discharge, a profuse white diarrhea, and weakness. The eyelids and uropygial glands are red and swollen. Birds that survive the acute stage show profound growth retardation, with loss of feathers and reddening of the skin, particularly on the back. Birds may stand in a “penguin-like” posture due to accumulation of ascitic fluid in the abdomen. In 2- to 4-wk-old birds, mortality can reach 10%, but morbidity levels may be much higher. No clinical signs are seen in older birds, although adults will respond immunologically. An enteric form of goose parvovirus infection has been documented to exist.

Lesions: Gross lesions include the presence of a fibrinous pseudomembrane covering the tongue and oral cavity, perihepatitis, pericarditis, pulmonary edema, liver dystrophy, and catarrhal enteritis. In acute cases, the heart is characteristically rounded at the apex, with a pale myocar-

dium. The main microscopic lesions are pronounced degenerative changes in the myocardial cells and the presence of Cowdry type-A intranuclear inclusion bodies.

Diagnosis: A presumptive diagnosis is based on the characteristic clinical course, age incidence, and gross and histologic lesions. Confirmation can be obtained after isolation of the parvovirus in cell cultures or embryonated eggs derived from susceptible geese and Muscovy ducks. Presence of the virus can be confirmed by electron microscopic examination of infected cultures and neutralization with specific goose parvovirus antiserum. Diagnosis can also be confirmed by direct detection of antigen or virus in tissues from infected birds, by immunofluorescence, or by the use of PCR. Serologic tests for goose parvovirus include virus neutralization, agar gel precipitation, immunofluorescence, and ELISA.

Although goose parvovirus causes disease in both geese and Muscovy ducks, Muscovy ducks are also infected with another antigenically related parvovirus. This virus causes serious disease in Muscovy ducklings, but not in goslings, and can be detected and differentiated using PCR combined with sequencing or restriction fragment length polymorphism. Differential diagnoses should also include duck viral enteritis (duck plague, *see* p 2799), which affects all types of waterfowl. Duck viral hepatitis (*see* p 2815) causes a fatal disease in ducklings but is not pathogenic for goslings or Muscovy ducklings. *Riemerella anatipestifer* and *Pasteurella multocida* may also cause high mortality in goslings and Muscovy ducklings but can be differentiated by bacterial isolation and identification.

Prevention and Treatment: Goslings should be hatched together only from flocks that are known to be free of goose parvovirus; many outbreaks are attributed to the practice of custom-hatching eggs from various sources. Eggs should be imported only from countries that can guarantee freedom from goose parvovirus. Geese that have survived an outbreak should not be used for breeding purposes. Both live, inactivated oil emulsion vaccines and baculovirus expressed VP2 capsid-based recombinant vaccines are available and are widely used in countries where the disease is endemic. Vaccination of breeding flocks induces high levels of maternal antibody in the progeny until ~2 wk of age.

HELMINTHIASIS

(Nematode and cestode infections)

Approximately 100 worm species have been recognized in wild and domestic birds in the USA. Nematodes (roundworms) are the most significant in number of species and in economic impact. Of species found in commercial poultry, the common roundworm (*Ascaridia galli*) is by far the most common. Field studies show that poultry maintained under free-range conditions may be heavily parasitized; therefore, control measures such as preventing infections or chemotherapy are likely to improve weight gain and egg production. In surveys of poultry raised under nonconfinement conditions throughout the world, an incidence of infection >80% is not uncommon.

Generally, nematodes have separate sexes that have morphologic differences;

eg, males of *Tetrameres* spp are elongated and slender, whereas gravid females are globe-shaped. The size and shape of nematode species vary widely; ascarids are sturdily and long (up to 4.5 in. [116 mm]); capillarids are more delicate, slender, and long (2.3 in. [60 mm]); and other nematodes are much shorter (0.08–0.48 in. [2–12 mm]).

Cestodes (tapeworms) also vary in size. *Raillietina* spp may be >12 in. (30 cm), whereas *Davainea proglottina* often is <0.16 in. (4 mm). The proglottids of individual tapeworms are hermaphroditic. Tapeworms have been recovered in the thousands from individual chickens and turkeys.

See TABLE 5 for information on common nematodes and cestodes of poultry.

TABLE 5 COMMON HELMINTHS OF POULTRY

Parasite	Host	Intermediate Host or Life Cycle	Organ Infected	Pathogenicity
NEMATODES				
<i>Amidostomum anseri</i>	Duck, goose, pigeon	Direct	Gizzard	Severe
<i>Ascaridia dissimilis</i>	Turkey	Direct	Small intestine	Moderate
<i>Ascaridia galli</i>	Chicken, turkey, duck, quail	Direct	Small intestine	Moderate
<i>Capillaria caudinflata</i>	Chicken, turkey, duck, game birds, pigeon	Earthworms	Small intestine	Moderate to severe
<i>Capillaria contorta</i>	Chicken, turkey, duck, game birds	None or earthworms	Mouth, esophagus, crop	Severe
<i>Capillaria obsignata</i>	Chicken, turkey, goose, pigeon, quail	Direct	Small intestine, ceca	Severe
<i>Cheilosporira hamulosa</i>	Chicken, turkey, game birds	Grasshoppers, beetles	Gizzard	Moderate
<i>Cyathostoma bronchialis</i>	Turkey, duck	Direct or earthworm	Trachea	Severe
<i>Cyrnea colini</i>	Turkey, game birds	Cockroaches	Proventriculus	Mild

(continued)

TABLE 5

COMMON HELMINTHS OF POULTRY (continued)

Parasite	Host	Intermediate Host or Life Cycle	Organ Infected	Pathogenicity
<i>Dispharynx nasuta</i>	Chicken, turkey, game birds, pigeon	Sowbugs	Proventriculus	Moderate to severe
<i>Gongylonema ingluvicola</i>	Chicken, game birds	Beetles, cockroaches	Crop, esophagus, proventriculus	Mild
<i>Heterakis gallinarum</i>	Chicken, turkey, duck, game birds	Direct	Ceca	Mild, but transmits agent of histomoniasis
<i>Heterakis isolonche</i>	Quail, duck, pheasant	Direct	Ceca	Severe
<i>Ornithostrongylus quadricaudatus</i>	Pigeon, dove	Direct	Small intestine	Severe
<i>Oxyspirura mansoni</i>	Chicken, turkey, guinea fowl, quail	Cockroaches	Eye	Moderate
<i>Strongyloides avium</i>	Chicken, turkey, quail, goose	Direct	Ceca	Moderate
<i>Subulura brumpti</i>	Chicken, turkey, duck, game birds	Earwigs, grasshoppers, beetles, cockroaches	Ceca	Mild
<i>Syngamus trachea</i>	Chicken, turkey, pheasant, quail	None or earthworm	Trachea	Severe
<i>Tetrameres americana</i>	Chicken, turkey, duck, game birds, pigeon	Grasshoppers, cockroaches	Proventriculus	Moderate to severe
<i>Trichostrongylus tenuis</i>	Chicken, turkey, duck, game birds, pigeon	Direct	Ceca	Severe
CESTODES				
<i>Choanotaenia infundibulum</i>	Chicken	House flies	Upper intestine	Moderate
<i>Davainea proglottina</i>	Chicken	Slugs, snails	Duodenum	Severe
<i>Metroliasthes lucida</i>	Turkey	Grasshoppers	Intestine	Unknown
<i>Raillietina cesticillus</i>	Chicken	Beetles	Duodenum, jejunum	Mild
<i>Raillietina echinobothrida</i>	Chicken	Ants	Lower intestine	Severe, nodules
<i>Raillietina tetragona</i>	Chicken	Ants	Lower intestine	Severe

Transmission: Modern confinement rearing of poultry has significantly reduced the frequency and variety of endoparasite infections, which are common in ranged birds and in backyard flocks. However, severe parasitism still may be seen in floor-reared layers, breeders, turkeys, or pen-reared game birds where management problems may exist. Contributing factors include the use of poorly managed built-up litter (which fosters the propagation of intermediate hosts and the accumulation of infective eggs) and resistance of the parasites to therapeutic drugs. Range infections of nematodes such as *Heterakis gallinarum* and *Syngamus trachea* may increase because of seasonal or climatic abundance of specific invertebrate intermediate hosts, eg, large numbers of earthworms brought to the surface by spring rains. Some species have been associated with large numbers of darkling beetles, which may act as mechanical vectors of infective eggs.

Nematodes have either a species-specific, direct life cycle with bird-to-bird transmission by ingestion of infective eggs or larvae, or an indirect cycle that requires an intermediate host (eg, insects, snails, or slugs). Eggs of many nematode species are resistant to low temperatures and disinfectants but may be more susceptible to heat and desiccation.

The life cycle of *A. galli* is simple and direct. Eggs in the droppings become infective in 10–12 days under optimal conditions. The infective eggs are ingested and hatch in the proventriculus, and the larvae live free in the lumen of the duodenum for the first 9 days. They then penetrate the mucosa, causing hemorrhages, return to the lumen by 17–18 days, and reach maturity at 28–30 days. Levels of infection are often underestimated, because early larval stages are barely visible and can remain for long periods within intestinal tissues, whereas adult stages in the lumen are generally fewer in number. Maturation of larval stages can be hampered by adult worm numbers, thereby increasing the time larval stages remain in intestinal tissues and continue to cause damage.

The life cycle of *H. gallinarum* is similar to that of *A. galli*. The greatest production of eggs for each egg ingested occurs in the ring-necked pheasant, followed by the guinea fowl and chicken. The larvae are closely associated with the cecal tissue, but a true tissue phase rarely occurs. Most of the adult worms are found at the blind end of the ceca. Earthworms may ingest the eggs of the cecal worm and serve as a

source of infection when ingested by poultry. Litter beetles may also serve as a mechanical vector.

The life cycle of *Capillaria* may be direct (*C. obsignata*), require an intermediate host such as earthworms (*C. caudinflata*), or be either direct or use earthworms (*C. contorta*). Larval development in the egg takes 8–15 days depending on temperature. Worms reach maturity in 20–26 days after ingestion by the final host.

The gapeworm *Syngamus trachea* inhabits the trachea and lungs of many domestic and various wild birds. Infection may occur directly by ingestion of infective eggs or larvae; however, severe field infection is associated with ingestion of transport hosts such as earthworms, snails, slugs, and arthropods (eg, flies). Many gapeworm larvae may encyst and survive within a single invertebrate for years. Although gapeworms are not a problem in confinement-reared poultry, they cause serious economic losses in game-farm pens and in range-reared chickens, pheasants, turkeys, and peacocks. *Cyathostoma bronchialis* is the gapeworm of geese and ducks.

Eggs of *Oryspirura mansonii*, Manson eyeworm, are deposited in the eye, reach the pharynx via the nasolacrimal duct, are swallowed, passed in the feces, and ingested by the Surinam cockroach, *Pycnoscelus surinamensis*. Larvae reach the infective stage in the cockroach. When infected intermediate hosts are eaten, liberated larvae migrate up the esophagus to the mouth and then through the nasolacrimal duct to the eye, where the cycle is completed. Other insect species may also serve as the intermediate host.

Cestodes require an intermediate host (eg, insects, crustaceans, earthworms, or snails). Floor layers, breeders, and broilers are infected with *Raillietina cesticillus* by

Heterakis gallinarum in the cecal pouches of a chicken. Courtesy of Dr. Jean Sander.

ingestion of the intermediate host, small beetles that breed in contaminated litter. Cage layers in unscreened houses may become infected with *Choanotaenia infundibulum* by eating its intermediate host, the house fly. Litter beetles in proximity may also serve as intermediate hosts.

More than 3,000 of the microscopic tapeworm *Davainea proglottina* have been recovered from a single bird. Several species of slugs and snails serve as intermediate hosts, and >1,500 infective parasites have been recovered from a single slug.

Pathogenesis and Clinical Findings:

Ascaridia, *Heterakis*, and *Capillaria* spp are widely distributed and cause such nonspecific signs as general unthriftiness, inactivity, depressed appetite, and retarded growth; in severe cases, death may result. A mere few ascarids may depress weight, and larger numbers may block the intestinal tract. Ascarids may migrate up the oviduct (via the cloaca) to become ensheathed later within the egg (an aesthetic, but not a public health, problem, avoidable by careful egg-candling before the release of eggs to market). *A. dissimilis* (turkey roundworm) may also migrate out of the intestine, through the portal system, and into the liver, causing hepatic granulomas.

H. gallinarum, a mild pathogen, in large numbers may cause thickening, inflammation, or nodulation in the cecal walls. Infection with *H. gallinarum* has been associated with cecal and hepatic granulomas. *Heterakis isolonche*, highly pathogenic in pheasants, may cause 50% mortality. *H. gallinarum* carries *Histomonas meleagridis*, the protozoan that causes histomoniasis (see p 2835).

C. contorta in the mucosae of the crop and esophagus, and *C. obsignata* in the wall of the small intestine, cause marked thickening and inflammation of the organs. Birds harboring large numbers of these threadlike worms become weak and emaciated and may die.

Young birds are the most severely affected by gapeworms. Sudden death and verminous pneumonia characterize early outbreaks. Signs of gasping, choking, shaking of the head, inanition, emaciation, and suffocation may follow. Necropsy reveals adult gapeworms obstructing the lumina of the trachea, bronchi, and lungs. Respiratory inflammation may be present. The blood-red, female gapeworm is usually found in copulation with a much smaller, paler male with its head embedded deep in the host tissue. The joined pair have a "Y"-shaped or forked appearance.

Oxyuris *mansonii* is a slender nematode, 12–18 mm long, found beneath the nictitating membrane of chickens and other fowl in tropical and subtropical regions. The parasite causes various degrees of inflammation, lacrimation, corneal opacity, and disturbed vision.

Among other nematodes, *Amidostomum anseris* attacks the gizzard lining of ducks and geese and causes dark discoloration, necrosis, and sloughing at the parasitic loci. *Dispharynx nasuta* causes ulceration, thickening, and maceration of the proventriculus; heavily infected birds may die. *Tetrameres americana*, a bright red worm discernible through the proventricular wall, causes diarrhea, emaciation, and with heavy infection, death. *Trichostrongylus tenuis* causes inflamed ceca, weight loss, anemia, and death, especially in young birds. *Ornithostrongylus quadriradiatus*, a blood-sucking parasite, causes pigeons to regurgitate bile-stained fluid mixed with food; greenish mucoid diarrhea from hemorrhagic intestines, emaciation, and death follow.

Most pathogenic tapeworms are found in the small intestine; the scolex, usually buried in the mucosa, generally causes mild lesions. *Davainea proglottina* may cause weight loss. *Railletina tetragona* causes weight loss and decreased egg production; *R. echinobothrida* produces granulomas at its attachment sites ("nodular disease").

Diagnosis: A reliable diagnosis can be made only by accurate identification of the individually recovered parasites; careful and complete necropsy techniques are essential. Only by specific recognition of the parasite can meaningful recommendations for flock therapy and management be made.

Treatment and Control: Improvement of management and sanitation in confined operations will generally lower the parasite levels in the birds. In range birds, the only option is to move to new pastures, although the benefit that may result will be of short duration. Application of approved insecticides to soil and litter when premises are unoccupied may interrupt the life cycle of the parasite by destroying its intermediate host. When the premises are restocked, groups of birds of different species or ages should be widely separated to avoid spread of parasites. Migration of litter beetles or other insects may infect new or widely separated housing.

Approved compounds are very limited in the USA. Because of frequently changing regulations, the status of any medication

should be checked before its administration. Approved drugs for the USA are listed online in the FDA's Green Book and in the commercially available Feed Compendium.

Only approved drugs may be used in birds producing eggs or meat for the commercial market. Label directions and recommended doses should be followed precisely, with scrupulous adherence to withdrawal times.

Piperazine compounds are relatively nontoxic and have been widely used against ascariasis. Because of this, drug resistance is widespread in many regions of the world. Several piperazine salts are available internationally. Because only the piperazine moiety is efficacious, doses should be calculated based on mg of active piperazine/bird. Piperazine should be completely consumed by birds within a few hours, because only relatively high concentrations of the drug eliminate worms. It may be given to chickens as a single dose, 50 mg/bird (<6 wk old), 100 mg/bird (≥6 wk old), in the feed at 0.2%–0.4% or in the drinking water at 0.1%–0.2%; it may be administered to turkeys at 100 mg/bird (<12 wk old) or 200 mg/bird (≥12 wk old). Some practitioners recommend the addition of molasses to unmedicated water after piperazine administration, so as to induce an osmotic flushing, theoretically removing any of the remaining worms from the intestinal tract. For severe cases, treatment can be repeated after 14 days. These medications must be withdrawn 14 days before slaughter. Piperazine is not approved in the USA for birds producing eggs for human consumption.

Fenbendazole is approved in the USA for use in growing turkeys at the rate of 14.5 g/ton of feed (16 ppm), fed continually as the sole ration for 6 days for the removal of *Ascaridia dissimilis* and *Heterakis gallinarum*. No withdrawal time is required. One study indicates a possible negative effect on sperm quality by the drug. It has been suggested that an alternative drug be used for treatment of breeding toms or that the sperm number and frequency of artificial inseminations be increased. Fenbendazole is not approved for use in other poultry in the USA but is effective against *Ascaris* when administered once at 10–50 mg/kg; if needed the treatment can be repeated after 10 days. At 10–50 mg/kg, fenbendazole when administered daily over 5 days is effective against *Capillaria*. Fenbendazole is also effective against other nematodes when administered at 10–50 mg/kg/day for 3–5 days or as a single dosage of 20–100 mg/kg, or added to the drinking water at 125 mg/L for 5 days or to the feed at 100 mg/kg. Fenbendazole should

not be administered during molt, because it may interfere with feather regrowth.

Hygromycin B given at 8–12 g/ton in feed is used to control ascarids, cecal worms, and capillarids in chickens. A withdrawal time of 3 days is required. Coumaphos, 0.004% in feed for 10–14 days for replacements, or 0.003% in feed for 14 days for layers, has been commonly used against capillarids. Chickens <8 wk old should not be given this medication, and it should not be used within 10 days of vaccination or other stress. In birds maintained on contaminated litter or exposed to infected birds, the medication regimen should be repeated using the same dosages as the first. There should be at least 3 wk between the first and second course of treatment. Hygromycin B is a cholinesterase inhibitor, and treated birds should not be exposed to other cholinesterase inhibitors (drugs, insecticides, pesticides, or chemicals) within 3 days before or after treatment.

As a treatment for Manson eyeworm, a local anesthetic can be applied to the eye, and the worms in the lacrimal sac exposed by lifting the nictitating membrane. A 5% cresol solution (1–2 drops) placed in the lacrimal sac kills the worms immediately. The eye should be irrigated with sterile water immediately to wash out the debris and excess solution. The eyes improve within 48–72 hr and gradually become clear if the destructive process caused by the parasite is not too far advanced.

The use of diatomaceous earth supplemented at 2% in feed and fed continuously lowers numbers of *Heterakis* and *Capillaria* in chickens. The efficacy of several essential oils have been measured, with inconsistent results.

Several compounds are reported to be effective against nematode infections but are not approved for use in poultry or other avian species in the USA. Three such compounds, tetranisole at 40 mg/kg, flubendazole at 30 ppm in feed, and ivermectin 1% at 10 mg/mL in water were effective in removing *A. galli*, *H. gallinarum*, and *Capillaria* in chickens. Pyrantel tartrate was more effective than pyrantel pamoate against the adult stage of *A. galli*, and it was somewhat effective against *Capillaria* when administered at 15–25 mg/kg. Levamisole administered at 25–30 mg/kg appears to be effective against *A. dissimilis*, *H. gallinarum*, and *C. obsignata*; it can also be given in the drinking water at 0.03%–0.06%. Phenothiazine has been used to treat cecal worms in chickens at 0.5 g/bird and in turkeys at 1 g/bird, given in 1 day. Combined

in drinking water as a 1-day treatment, phenothiazine (0.5%–0.56%) and piperazine (0.11%) have been used to treat heterakids and ascarids; this drug combination is no longer approved for poultry in the USA. Methyridine injected SC at a dose of 25–45 mg/bird is effective in clearing *C. obsignata*. In pigeons, a SC injection of 1 mL of 10% methyridine in the pectoral region or leg of pigeons removed *Capillaria*, but the drug must be handled with care because contact with skin may produce lesions. Coumaphos removes *Capillaria* in quail. Haloxon at 25 and 50 mg/kg, or at 750 ppm in the feed for 5–7 days, has good activity against *Capillaria* in chickens and quail.

Fenbendazole at 20 mg/kg for 3–4 days effectively removes gapeworms in pheasants. Toxicity has been reported in pigeons that received fenbendazole at the rate of 30 mg/kg for 5 days. Thiabendazole administered at 0.05% in the feed continually for 2 wk can be used for treatment of gapeworms in pheasants, and when given continually for ≥4 days is said to help prevent and control infections. Withdrawal of 21 days is required for meat consumption; specific precautions should be observed in feeds containing bentonite. Tetramisole at 3.6 mg/kg for 3 consecutive days in the drinking water removes gapeworms. Poultry treated while larvae are migrating in the body develop immunity to gapeworms, even though therapy may abort larval migration. Levamisole fed at a level of 0.04% for 2 days or at 2 g/gal. drinking water for 1 day each month has proved to be an effective control in game birds. Kiwis are reported to be acutely sensitive to levamisole at doses well within the safe range for domesticated poultry. Mebendazole fed prophylactically at 64 ppm or curatively at

125 ppm is effective in turkey poult. Cambendazole provided control when given in three treatments of 50 mg/kg for chickens and 20 mg/kg for turkeys. Albendazole administered as a single oral suspension (5 mg/kg bird weight) was reported effective against *A. galli*, *H. gallinarum*, and *C. obsignata*. The drug also has been reported effective against cestodes if administered at 20 mg/kg. There are no published withdrawal times. Nitarson at 170 g/ton (0.01875%) of feed has been reported to reduce *A. dissimilis* fecundity and worm burden in chickens and turkeys.

There have been some reports of experimental drug treatment for other nematodes. Cambendazole (60 mg/kg), pyrantel (100 mg/kg), citarin (40 mg/kg), mebendazole (10 mg/kg for 3 days), and fenbendazole have been reported to be effective against *Amidostomum anseris*. *Trichostrongylus tenuis* is controlled by cambendazole (30 mg/kg), pyrantel (50 mg/kg), thiabendazole (75 mg/kg), mebendazole (10 mg/kg for 3 days), and citarin (40 mg/kg). At recommended levels for chickens, mebendazole has some reported effect against *Dispharynx nasuta*, tetramisole against *Subulura brumpti* and *Strongyloides avium*, and piperazine against *Tetrameres*.

Poultry producers wanting to treat for tapeworms should be aware that expulsion of the parasite will be a short-term remedy if the scolex is not removed or if the intermediate host is not eliminated as a source of reinfection. Butynorate in combination with piperazine and phenothiazine as a feed additive or individual tablets has shown some efficacy. Other promising experimental drugs include chlorophene and niclosamide. None is approved in the USA.

HEMORRHAGIC ENTERITIS/ MARBLE SPLEEN DISEASE

Hemorrhagic enteritis is an acute GI disorder affecting young turkeys ≥4 wk old. In its most severe form, it is characterized by depression and hemorrhagic droppings. Mortality may be increased; however, this is rare because of extensive use of vaccines. Marble spleen disease is an acute respiratory disease of pheasants characterized by depression, enlarged mottled spleens, pulmonary congestion, and death. Both diseases are caused by similar viruses.

Species-specific differences in clinical response are thought to be related to differences in the target organs for anaphylaxis and variation in viral pathotype. Infection with less virulent pathotypes in either host often may go undetected until secondary bacterial infections begin to develop as a result of viral-induced immunosuppression.

Similar diseases have been seen sporadically in other species of birds such

as chickens (splenomegaly), guinea fowl, peafowl, and chukar partridges.

Etiology and Epidemiology:

The etiologic agent is a nonenveloped, icosahedral DNA virus, 70–90 nm in diameter. It is a member of the family Adenoviridae and the genus *Siadenovirus*. Based on differences in presentation within host species, numerous viral pathotypes appear to exist. These differ slightly at the DNA level but are indistinguishable serologically.

Both hemorrhagic enteritis and marble spleen disease are geographically widespread and considered endemic in areas where turkeys and pheasants are raised commercially. The usual route of infection is oral, and virus is often introduced onto previously uninfected premises via personnel or equipment contaminated with infectious feces. Turkey poults and pheasants 3–4 wk old are resistant to infection because of age-related resistance or, more commonly, the presence of maternal antibody. The virus may survive under moist conditions (ie, in litter) well beyond the refractory period. As infection begins to cycle through a flock, large quantities of virus are shed in the feces, which facilitates rapid spread through susceptible birds. Morbidity usually approaches 100% for both hemorrhagic enteritis and marble spleen disease.

Clinical Findings: In commercial operations, hemorrhagic enteritis typically affects turkeys 6–12 wk old but is most common between 7–9 wk of age. In outbreaks involving highly virulent pathotypes, clinical signs can include depression, pallor, and bloody droppings. Acute mortality can range from 1%–60%, with an average of 10%–15% throughout a 2-wk period. Birds that survive the acute phase experience a transient immunosuppression related to the lymphotropic, lymphocytopathic nature of the virus. This often manifests itself in the form of secondary bacterial infections, eg, colibacillosis (see p 2814) ~10–14 days after exposure to the virus. Thus, a second peak in mortality, potentially overlapping the first, may be seen and, in less virulent outbreaks, may actually dominate the clinical picture. The second wave of mortality often lasts 2–4 wk and is characterized by lesions commonly associated with bacterial respiratory disease or septicemia, eg, fibrinopurulent pneumonia, airsacculitis, pericarditis, peritonitis, perihepatitis, hepatomegaly, and

splenomegaly. Concomitant or prior exposure to necrotic enteritis (see p 2802), coccidiosis (see p 2791), Newcastle disease virus (see p 2856), *Bordetella avium* (see p 2907), or *Mycoplasma gallisepticum* and *M synoviae* (see p 2841) can exacerbate the problem. Similar multiple agent interactions have been implicated in mortality associated with the use of vaccines for hemorrhagic enteritis.

Marble spleen disease typically affects pheasants 3–8 mo old. Onset is acute, with dyspnea, asphyxiation, and sudden death occurring as a result of pulmonary congestion and edema. Mortality is commonly 2%–3% but can reach 15%. Secondary bacterial infections as a result of immunosuppression have also been noted.

Lesions: Necropsy of moribund or dead birds infected with hemorrhagic enteritis virus reveals gross congestion and occasional intraluminal hemorrhage in the proximal small intestine. The spleen is usually enlarged, friable, and mottled white, except in birds that have hemorrhaged extensively. Hemorrhage in the intestine is not common in field cases. Histopathologic changes in the duodenum include congestion, hemorrhage, and necrosis of the intestinal epithelium. This lesion in particular is thought to be the result of a virally induced, cytokine-mediated anaphylactic reaction, with the GI tract being considered the target shock organ in turkeys. Basophilic intranuclear inclusions can be found in lymphocytes and macrophages in a variety of tissues (eg, intestine, liver, and lungs) but predominantly in the spleen, where lymphoreticular hyperplasia and lymphoid necrosis are noted. Intranuclear inclusions in the renal tubular epithelial cells of the kidneys can be seen in turkeys that have recovered from hemorrhagic enteritis.

Enlarged, mottled spleen in a turkey with hemorrhagic enteritis. Courtesy of Dr. Jean Sander.

On histopathologic evaluation of pheasants with marble spleen disease, flooding of the atria and tertiary bronchi with fibrin and RBCs, as well as generalized vascular congestion and focal necrosis, are often seen in the lung. As with hemorrhagic enteritis, this response may be anaphylactic in nature, with the lung being considered the target shock organ in the pheasant. Splenomegaly with lymphoreticular hyperplasia and lymphoid necrosis also occur and are the characteristic lesions for which marble spleen disease is named. Basophilic or magenta-colored intranuclear inclusions may be found in a variety of tissues excluding the GI tract, with the highest concentration of virus found in the spleen.

Diagnosis: Diagnosis of virulent outbreaks of hemorrhagic enteritis or marble spleen disease can often be made based on clinical signs and gross lesions. Confirmation is by histopathology and the presence of seroprecipitating virus in the spleen as determined by agar gel immunodiffusion. PCR techniques to detect hemorrhagic enteritis viral DNA in tissue have also been described and are in regular use in select laboratories. To determine whether hemorrhagic enteritis or marble spleen disease is a predisposing factor in cases of bacterial respiratory disease or septicemia, or to verify a primary diagnosis, acute and convalescent sera (3 wk apart) can be tested using either agar gel immunodiffusion or ELISA. In turkeys, differential diagnoses include colibacillosis, pasteurellosis, paratyphoid, and erysipelas. Reticuloendotheliosis or lymphoproliferative disease should be considered when lymphoreticular hyperplasia is the predominant lesion. GI lesions without splenic involvement should evoke consideration of other viral, bacterial,

parasitic, and toxic enteritides of turkeys. In pheasants with acute respiratory disease, differential diagnoses include Newcastle disease, avian influenza, and in the case of birds reared in confinement, gaseous toxins.

Treatment, Control, and Prevention:

Virulent outbreaks of hemorrhagic enteritis have been successfully treated and controlled by SC injection of exposed birds with 0.5–1 mL of antiserum obtained from recovered flocks. It is presumed that a similar approach may be effective for pheasants. In anticipation of secondary bacterial complications, antibiotics may be used, but if possible, an informed choice should be made based on current antibiotic susceptibility profiles for locally obtained *Escherichia coli* isolates. In addition to good biosecurity, prevention hinges on the use of vaccines administered in the water at ~4–5 wk of age. Commercially available tissue culture products and crude splenic preparations containing avirulent isolates produce lifelong protection. Quality control on crude splenic preparations, such as examining them for bacteria, *Mycoplasma*, and other viruses, should be done before they are prepared. A subunit vaccine to prevent hemorrhagic enteritis in turkeys has been described in Europe.

Vaccines intended for use in turkeys should not be used in pheasants, and vice versa, because the avirulent isolates used for vaccinating one species are typically virulent in the other. Because of the potential for interaction with other agents, including live vaccines, regular disease monitoring and careful integration of hemorrhagic enteritis and marble spleen disease vaccines into flock vaccination protocols is encouraged. Intuitively, vaccines should not be administered to birds exhibiting signs of illness or within 2 wk of any other vaccination.

HISTOMONIASIS

(Blackhead, Infectious enterohepatitis)

Histomoniasis is caused by a protozoan that infects the ceca, and later the liver, of turkeys, chickens, and occasionally other galliform birds. In turkeys, most infections are fatal, whereas in other galliforms susceptibility varies between species and breeds.

Etiology: The causative agent of histomoniasis is the anaerobic, single cell protozoan parasite *Histomonas meleagridis* that can exist in flagellated (8–15 µm in diameter) and amoeboid (8–30 µm in diameter) forms. *Histomonas* is most often transmitted in embryonated eggs of the

cecal nematode *Heterakis gallinarum*. A large percentage of chickens and other gallinaceous birds harbor this worm, which serves as a reservoir. Three species of earthworms can act as vectors for *H. gallinarum* larvae containing *H. meleagridis*, which are infective to both chickens and turkeys. *H. meleagridis* survives for long periods within *Heterakis* eggs, which are resistant and may remain viable in the soil for years. Histomonads are released from *Heterakis* larvae in the ceca a few days after entry of the nematode and replicate rapidly in the ceca. The parasites migrate into the submucosa and muscularis mucosae and cause extensive and severe necrosis. Histomonads reach the liver either by the vascular system or via the peritoneal cavity, and rounded necrotic lesions quickly appear on the liver surface. Histomonads interact with other gut organisms, such as bacteria and coccidia, and depend on these for full virulence. In turkeys, transmission is by direct cloacal contact with infected birds or via fresh droppings, resulting in histomoniasis quickly spreading throughout the flock. Infection has not been shown to spread in this manner in chickens.

Traditionally, histomoniasis has been thought of as affecting turkeys, while doing little damage to chickens. However, outbreaks in chickens may cause high morbidity, moderate mortality, and extensive culling. Liver lesions tend to be less severe in chickens but often involve secondary bacterial infections. Morbidity can be especially high in young layer or breeder pullets. Layer flocks recover but lack uniformity. Experimental infections with *Histomonas* of 16-wk-old layers have demonstrated reduced egg production during infection. Tissue responses to infection may resolve in 4 wk, but birds may be carriers for another 6 wk.

Clinical Findings: Signs of histomoniasis are apparent in turkeys 7–12 days after infection and include listlessness, reduced appetite, drooping wings, unkempt feathers, and yellow droppings in the later stages of the disease. The origin of the name “blackhead” is obscure and misleading, with only a few birds displaying a cyanotic head. Young birds have a more acute disease and die within a few days after signs appear. Older birds may be sick for some time and become emaciated before death.

Lesions: The primary lesions of histomoniasis are in the ceca, which exhibit marked inflammatory changes and ulcerations, causing a thickening of the cecal wall. Occasionally, these ulcers erode

Liver lesions, an enlarged ceca with cores, and inflammation seen in multiple tissues of a turkey with histomoniasis. Courtesy of Dr. Larry R. McDougald and Dr. Robert B. Beckstead.

the cecal wall, leading to peritonitis and involvement of other organs. The ceca contain a yellowish green, caseous exudate or, in later stages, a dry, cheesy core. Liver lesions are highly variable in appearance; in turkeys, they may be up to 4 cm in diameter and involve the entire organ. In some cases, the liver will appear green or tan. The liver and cecal lesions together are pathognomonic. However, the liver lesions must be differentiated from those of tuberculosis, leukosis, avian trichomonosis, and mycosis. Lesions are also seen in other organs, such as the kidneys, bursa of Fabricius, spleen, and pancreas. Studies by PCR show that *Histomonas* DNA can be found in the blood and in the tissues of most organs, whether lesions are present or not. Histopathologic examination is helpful for differentiation of diseases.

Histomonads are intercellular, although they may be so closely packed as to appear intracellular. The nuclei are much smaller than those of the host cells, and the cytoplasm less vacuolated. Scrapings from the liver lesions or ceca may be placed in isotonic saline solution for direct microscopic examination; *Histomonas* spp must be differentiated from other cecal flagellates. Molecular diagnosis is possible with published PCR primers.

Prevention and Treatment: Because healthy chickens and gamebirds often carry the cecal worm vector, any contact between turkeys and other galliforms should be avoided and care should be taken to reduce the worm population. Worm eggs, from contaminated soil, can be tracked inside by workers, causing infection. Arthropods such as flies may also serve as mechanical vectors. Because *H. gallinarum* ova can

survive in soil for many months or years, turkeys should not be put on ground contaminated by chickens. Once established in a turkey flock, infection spreads rapidly without a vector through direct contact. Dividing a facility into subunits using barriers can contain the outbreaks to specific units. Histomonads that are shed directly into the environment die quickly. Thus, in a turkey facility, where *Heterakis* is unable to complete its life cycle, decontamination is not required.

Immunization has only been partially successful in controlling histomoniasis, and reports differ on its effectiveness. The immune response of turkeys to live attenuated *Histomonas* requires 4 wk to develop. Vaccination of 18-wk-old pullets 5 wk before experimental infection has been shown to prevent a drop in egg production. Most workers have concluded that immunization of birds against this disease

using live cultures is not practical. Killed organisms stimulate some immunity when given SC or IP but do not offer protection.

No drugs are currently approved for use as treatments for histomoniasis. Nitarsone is available for prophylaxis by feed medication. Nitarsone is mixed with the feed at 0.01875% and fed continually. A 5-day withdrawal period is required for animals slaughtered for human consumption. Under most conditions, nitarsone is effective, although some outbreaks in turkeys on medication have been reported. Historically, nitroimidazoles such as ronidazole, ipronidazole, and dimetridazole were used for prevention and treatment and were highly effective. Some of these products can be used by veterinary prescription in non-food-producing birds. Frequent worming of chickens with benzimidazole anthelmintics helps reduce exposure to heterakiid worms that carry the infection.

INFECTIOUS BURSAL DISEASE

(Gumboro disease)

Infectious bursal disease (IBD) is seen in domestic chickens worldwide. It can present as a clinical or subclinical disease, but immunosuppression and related secondary infections are typically seen. Severity of the immunosuppression depends on the virulence of the infecting virus and age of the host.

Etiology and Transmission: IBD is caused by a birnavirus (infectious bursal disease virus; IBDV) that is most readily isolated from the bursa of Fabricius but may be isolated from other organs. It is shed in the feces and transferred from house to house by fomites. It is very stable and difficult to eradicate from premises.

Two serotypes of IBDV have been identified. The serotype 1 viruses cause disease in chickens and, within them, antigenic variation can exist between strains. Antigenic drift is largely responsible for this antigenic variation, but antigenic differences can also occur through genome homologous recombination. Serotype 2 strains of the virus infect chickens and turkeys but have not caused clinical disease or immunosuppression in these hosts. IBDVs have been identified in other avian species, including penguins, and antibodies

to IBDV have been seen in several wild avian species. The contribution of IBDV to disease in these wild birds is unknown.

Clinical Findings: IBD is highly contagious; results of infection depend on age and breed of chicken and virulence of the virus. Infections may be subclinical or clinical. Infections before 3 wk of age are usually subclinical. Chickens are most susceptible to clinical disease at 3–6 wk of age when immature B cells populate the bursa and maternal immunity has waned, but severe infections have occurred in Leghorn chickens up to 18 wk of age.

Early subclinical infections are the most important form of the disease because of economic losses. They cause severe, long-lasting immunosuppression due to destruction of immature lymphocytes in the bursa of Fabricius, thymus, and spleen. The humoral (B cell) immune response is most severely affected; the cell-mediated (T cell) immune response is affected to a lesser extent. Chickens immunosuppressed by early IBDV infections do not respond well to vaccination and are predisposed to infections with normally nonpathogenic viruses and bacteria. Common diseases are usually exacerbated by IBDV infections.

Some strains of IBDV can cause subclinical infections in older birds (3–6 wk old), which leads to losses from poor feed efficiency and longer times to market. In these cases, the immunosuppression is usually transient, and convalescent birds may recover most or all of their humoral immune function. However, secondary infections that occur during the transient immunosuppression can cause significant economic losses.

In clinical infections, onset of the disease occurs after an incubation of 3–4 days. Chickens may exhibit severe prostration, incoordination, watery diarrhea, soiled vent feathers, vent picking, and inflammation of the cloaca. Flock morbidity is typically 100%, and mortality can range from 5%–20%. Recovery occurs in <1 wk, and broiler weight gain is delayed by 3–5 days. The presence of maternal antibody will modify the clinical course of the disease.

Virulence of field strains of the virus varies considerably. Viruses that range from naturally attenuated to very virulent (vv) have been observed. The vvIBDV strains that can cause high mortality (>20%) were first detected in Europe. They spread throughout the Middle East, Asia, and Africa, were detected in South and Central America in 1999, and in the USA in 2009.

Lesions: At necropsy, the lesions seen will depend on the strain of IBDV. For strains that cause a clinical disease, the cloacal bursa is swollen, edematous, yellowish, and occasionally hemorrhagic, especially in birds that died of the disease. Strains of vvIBDV cause similar cloacal bursa lesions, and congestion and hemorrhage of the pectoral and leg muscles can also occur. IBDV strains that cause subclinical disease (sometimes referred to as variant strains) cause atrophy of the

cloacal bursa without inflammation.

Chickens that have recovered from IBDV infections have small, atrophied, cloacal bursas due to the destruction and lack of regeneration of the bursal follicles.

Diagnosis: Molecular diagnostic assays are most often used to identify IBDV in diagnostic samples. They use reverse-transcriptase PCR to identify the viral genome in bursa tissue. Sequence analysis of the VP2 coding region has been used to further characterize the viruses. Samples for molecular diagnostic testing are typically collected after maternal antibodies have waned. IBDV may be isolated in 8- to 11-day-old, antibody-free chicken embryos with inocula from birds in the early stages of disease. The chorioallantoic membrane is more sensitive to inoculation than is the allantoic sac. Some strains of IBDV may also be isolated in cell cultures that include chicken embryo fibroblasts, cells from the cloacal bursa, and established avian and mammalian cell lines. Cell culture–adapted strains of IBDV produce a cytopathic effect and may be used for quantitative titration of the virus and virus-neutralization assays.

Control: There is no treatment. Rigorous disinfection of contaminated farms after depopulation has achieved limited success. Live vaccines of chicken embryo or cell-culture origin and of varying low pathogenicity can be administered by eye drop, drinking water, or SC routes at 1–21 days of age. Replication of these vaccines and thus the immune response can be altered by maternal antibody, although the more virulent vaccine strains can override higher levels of maternal antibody. Vectored vaccines that express the IBDV VP2 protein in herpesvirus of turkeys (HVT) can be used in ovo or at hatch. These HVT-IBDV vaccines are not affected by maternal antibodies. Vaccines that use live-attenuated viruses bound to antibodies (immune-complex vaccines) are also available for in ovo or at hatch administration.

High levels of maternal antibody during early brooding of chicks in broiler flocks (and in some commercial layer operations) can minimize early infection, subsequent immunosuppression, or both. Breeder flocks should be vaccinated one or more times during the growing period, first with a live vaccine and again just before egg production with an oil-adjuvanted, inactivated vaccine. Inactivated vaccines of chicken embryo, bursa, or cell-culture origin are available. The latter vaccines induce higher, more uniform, and more persistent

Enlarged, hemorrhagic bursa of Fabricius in a chicken infected with very virulent infectious bursal disease virus. Courtesy of Dr. Daral J. Jackwood.

levels of antibody than do live vaccines. The immune status of breeder flocks should be monitored periodically with a quantitative serologic test such as virus neutralization or ELISA. If antibody levels decrease, hens should be revaccinated to maintain adequate immunity in the progeny.

The goal of any vaccination program for IBD should be to use vaccines that most closely match the antigenic profile of the field viruses. Diagnostic testing for the genomic sequences of field strains can be used to select the most appropriate vaccination program.

LISTERIOSIS

Listeriosis is caused by the bacterium *Listeria monocytogenes*. Although many species of birds, including chickens, turkeys, pigeons, ducks, geese, canaries, and cockatiels, are susceptible to infection, clinical disease in birds is rare. Generally, young birds are more susceptible to infection and more likely to develop clinical disease than older birds. In chickens, the disease occurs sporadically as either septicemia or encephalitis.

Etiology, Epidemiology, and

Pathogenesis: *L. monocytogenes* is a gram-positive, nonsporeforming, facultative intracellular, rod-shaped bacterium. It is widely distributed and commonly found in the environment. In temperate zones, the primary habitats of the organism are soil and decaying vegetation. The organism is common in poorly preserved stored corn silage. *L. monocytogenes* has been isolated from the intestinal tract of healthy animals, including different species of mammals, birds, and fish. Transmission occurs via ingestion, inhalation, or wound contamination. In ruminants, the encephalitic form of listeriosis develops after entry of the organism through minor injuries in the conjunctiva or oral and nasal mucosa with subsequent migration along peripheral nerves to the brain. It is unknown if this same route of infection occurs in birds. Contamination of poultry farms with fecal material from nearby food animal farms (eg, cattle or swine farms) is an important source of infection, especially after a rain or flooding. Wounds from beak trimming and vaccine injection are possible sites of entry for the organism.

Clinical Findings: In the septicemic form of listeriosis, clinical signs are not specific and include depression, lethargy, and sudden death. In the encephalitic form,

lateral recumbency, ataxia, torticollis, leg paddling, opsisthotonos, paresis, and paralysis have been seen.

Lesions: Birds affected with the septicemic form of listeriosis often have extensive degeneration and necrosis of the myocardium, with splenomegaly, necrotic foci in the liver, and pericarditis. Other lesions reported in broilers include ascites and petechial hemorrhages in the myocardium, liver, kidneys, and spleen. In the encephalitic form, no gross lesions are seen in the brain, but histopathologic lesions are remarkable and include disseminated microabscesses, extensive fibrinous thrombosis, foci of hemorrhages, necrosis (malacia) of the parenchyma, perivascular cuffs of lymphocytes and macrophages, and gliosis. Gram stain of tissues reveals typical gram-positive bacteria within the lesions. Lesions are found in the medulla oblongata, where they are generally most severe, and in the optic lobes and cerebellum.

Diagnosis: In the septicemic form, gross lesions should arouse suspicion, and histopathologic lesions should allow preliminary diagnosis of bacterial septicemia. Diagnosis is confirmed by immunohistochemistry to demonstrate *L. monocytogenes* in the tissues or by isolation of the organism, usually from the liver and/or spleen in the septicemic form and brain in the encephalitic form. Direct culture of affected tissues, especially the brain, may not always be successful because of the low concentration of organisms in affected tissues. Recovery of *L. monocytogenes* increases significantly if a portion of the specimen is refrigerated for 4–8 wk and subcultured weekly. Alternatively, tissue may be macerated or blended with a general nutrient broth (eg, trypticase soy broth, brain heart infusion) at a ratio of 1:10. The broth media is incubated at 35°C (95°F) for 5–7 days and examined daily for growth.

Differential diagnoses for septicemic listeriosis include other bacterial septicemias such as colibacillosis, pasteurellosis, and erysipelas. For encephalitic listeriosis, differential diagnoses include viral encephalitides, eg, Marek's disease and exotic Newcastle disease. With the latter, neurologic signs (torticollis, opisthotonos) typically follow high mortality in the flock, and lesions of the disease are present in visceral organs.

Treatment and Prevention: Antibiotics may be used successfully to treat the septicemic form of the disease. In vitro, *L. monocytogenes* is susceptible to penicillin, tetracycline, erythromycin, gentamicin, and

trimethoprim-sulfamethoxazole. Treatment of the encephalitic form is usually unsuccessful. Prevention should focus on identifying and eliminating potential sources of infection.

Zoonotic Risk: Listeriosis is a serious zoonotic disease. *L. monocytogenes* is recognized as an important foodborne pathogen in people and is of great concern to the public and poultry industry. Outbreaks of listeriosis usually follow exposure to raw or uncooked poultry products but have also occurred after contaminated ready-to-eat poultry meat products were eaten.

MALABSORPTION SYNDROME

(Runting-stunting syndrome, Pale bird syndrome)

Malabsorption syndrome is a transmissible disease characterized by stunted growth and a lack of skin pigmentation in growing chickens, most commonly broiler breeds. Turkeys may also be affected; in these birds, it resembles poult enteritis mortality syndrome. The disease has been identified in virtually all countries in which intensive poultry production occurs. It has been associated with several different enteric viruses and appears to be multifactorial, although the true etiology remains to be identified. Poor management may contribute to the problem.

Etiology and Transmission: The disease has been reproduced with bacteria-free intestinal homogenates, suggesting a viral origin. Enteroviruses, parvoviruses, astroviruses, caliciviruses, arenaviruses, togaviruses, reoviruses, and rotaviruses have been implicated. Enteroviruses, reoviruses, and mycotoxins have been considered the most likely etiologic factors, although recent reports suggest an important role for astroviruses and unusual parvoviruses. A problem hampering the understanding of the etiology is the inability to isolate these viruses. Because the disease is seen in very young chicks, it is likely the viruses are vertically transmitted, although fecal/oral spread occurs after hatching. The involvement of feedborne mycotoxins is not well understood.

Clinical Findings: The disease is typically recognized in broiler chicks

1–3 wk old. It is characterized by uneven growth; temporary stunting; permanent runting; lack of pigmentation in the skin, feet, or beak; slow feathering; broken or twisted feathers (“helicopter wings”); undigested feed in the feces; and poor feed conversion ratios. Diarrhea is common during the initial phases, and eating feces is seen. Other signs include lameness, osteodystrophy, and secondary encephalomalacia. Severely affected birds do not respond immediately to changes in feed or management practices and are usually culled from flocks before processing. The number affected in a flock can vary from a few to 90%.

Lesions: The severity and type of lesions resulting from both field and laboratory infections vary with the particular agents or combinations of agents involved. Lesions often include enlarged proventriculi, small gizzards, pancreatic atrophy, and orange mucus in the small-intestinal lumen. No consistent microscopic lesions are found, although cystic lesions in the small intestine have been described, and sometimes changes are present in the bursa and thymus. Encephalomalacia or rickets may be seen occasionally, presumably as a result of malabsorption or malassimilation of nutrients.

Diagnosis: Clinical signs and postmortem lesions permit a presumptive diagnosis. Because of the complex etiology and the

presence of enteric viruses in normal flocks, laboratory investigations may be difficult to interpret, particularly because virus culture may be difficult or impossible. Poor early management of flocks (especially feed and water supply and temperature control) may lead to a similar picture in the absence of specific infection.

Prevention and Control: There is no effective treatment for severely affected birds. Good broiler farm hygiene will reduce the burden of challenge caused by multiple infectious organisms. Good flock nutrition

and sanitation and avoidance of intercurrent disease are beneficial. No vaccines prevent malabsorption syndrome. Some reovirus vaccines are marketed to prevent the stunting and poor feed conversions due to pathogenic reoviruses. Feeds should be analyzed for dietary toxins, and high levels of toxins should not knowingly be fed to commercial poultry. Antibiotics and vitamin supplements can be helpful.

Zoonotic Risks: There have been no reported zoonotic risks associated with malabsorption syndrome.

MYCOPLASMOSIS

Mycoplasmas are bacteria that lack a cell wall and are the smallest prokaryotes (0.2–0.8 μm in diameter). They have complex nutritional requirements but will grow on specialized artificial medium containing serum. Growth in broth and on agar media is slow (5–21 days), and the small (0.1–1 mm diameter) colony morphology typically has a “fried egg” appearance under low magnification. Mycoplasmas do not survive for more than a few days outside the host and are vulnerable to common disinfectants.

Several *Mycoplasma* species have been isolated from avian hosts; *M. gallisepticum*, *M. synoviae*, *M. meleagridis*, and *M. iowae* are the most important. Each has distinctive epidemiologic and pathologic characteristics.

MYCOPLASMA GALLISEPTICUM INFECTION

(Chronic respiratory disease, Infectious sinusitis)

M. gallisepticum is commonly involved in the polymicrobial “chronic respiratory disease” of chickens; in turkeys, it frequently results in swollen infraorbital sinuses and is called “infectious sinusitis.” These diseases affect chickens and turkeys worldwide, causing the most significant economic losses in large commercial operations, and are commonly seen in noncommercial flocks. Infection also occurs in pheasants, chukar partridges, peafowl, pigeons, quail, ducks, geese, and psittacine birds. Songbirds are generally

resistant, although *M. gallisepticum* causes conjunctivitis in wild house finches (and some similar species) in North America.

M. gallisepticum is the most pathogenic avian mycoplasma; however, considerable strain variability is manifest in a range of host susceptibility, virulence, clinical presentation, and immunologic response. Integral membrane surface proteins (adhesins) that attach to receptors on host cells, allowing for colonization and infection, are important virulence factors involved in antigenic variation and immune evasion.

Epidemiology and Transmission:

M. gallisepticum is transmitted vertically within some eggs (transovarian) from infected breeders to progeny, and horizontally via infectious aerosols and through contamination of feed, water, and the environment, and by human activity on fomites (shoes, equipment, etc.). Infection may be latent in some birds for days to months, but when birds are stressed horizontal transmission may occur rapidly via aerosols and the respiratory route, after which infection and clinical disease spread through the flock. Flock-to-flock transmission occurs readily by direct or indirect contact from the movement of birds, people, or fomites from infected to susceptible flocks. Some potential reservoirs of *M. gallisepticum* in the USA are noncommercial (backyard) flocks, multiple-age layer flocks, and some free-ranging songbird species. Good management and biosecurity practices are necessary to ensure that *M. gallisepticum*

infections are not introduced to commercial poultry from these and other sources. In many outbreaks, the source of infection is unknown. Cold weather, poor air quality or crowding, concurrent infections, and some live virus vaccinations may facilitate infection, disease, and transmission.

Epithelium of the conjunctiva, nasal passages, sinuses, and trachea are most susceptible to initial colonization and infection; however, in severe, acute disease, infection may also involve the bronchi, air sacs, and occasionally lungs. Once infected, birds may remain carriers for life. There is a marked interaction (polymicrobial disease) between respiratory viruses, *Escherichia coli*, and *M gallisepticum* in the pathogenesis and severity of chronic respiratory disease.

Clinical Findings and Lesions: In chickens, infection may be inapparent or result in varying degrees of respiratory distress, with slight to marked rales, difficulty breathing, coughing, and/or sneezing. Morbidity is high and mortality low in uncomplicated cases. Nasal discharge and conjunctivitis with frothiness about the eyes may be present. The disease is generally more severe in turkeys than in chickens, and swelling of the infraorbital sinuses is common. Feed efficiency and weight gains are reduced. Commercial broiler chickens and market turkeys may suffer high condemnations at processing due to airsacculitis. In laying flocks, birds may fail to reach peak egg production, and the overall production rate is lower than normal.

Turkey infected with *M gallisepticum* has clear-mucoïd and dried nasal exudate and a swollen infraorbital sinus. Courtesy of North Carolina State University Poultry Health Management.

Uncomplicated *M gallisepticum* infections in chickens result in relatively mild catarrhal sinusitis, tracheitis, and airsacculitis. *E coli* infections are often concurrent and result in severe air sac thickening and turbidity, with exudative accumulations, adhesive pericarditis, and fibrinous perihepatitis. Turkeys develop severe mucopurulent sinusitis and varying degrees of tracheitis and airsacculitis. Microscopically, involved mucous membranes are thickened, hyperplastic, necrotic, and infiltrated with inflammatory cells. The mucosal lamina propria contains focal areas of lymphoid hypoplasia and germinal center formations.

Diagnosis: History, clinical signs, and typical gross lesions may be suggestive of *M gallisepticum* infection. Serology by agglutination and ELISA methods are commonly used for surveillance. Hemagglutination-inhibition is used as a confirmatory test, because nonspecific false agglutination reactions may occur, especially after injection of inactivated oil-emulsion vaccines or infection with *M synoviae*. *M gallisepticum* should be confirmed by isolation from swab samples of infraorbital sinuses, nasal turbinates, choanal cleft, trachea, air sacs, lungs, or conjunctiva. Primary isolation is made in mycoplasma medium containing 10%–15% serum. Colonies on agar medium are used for species identification by immunofluorescence with species-specific antibodies. PCR can also be used for detection of *M gallisepticum* DNA using swabs taken directly from infected sites (choana, sinuses, trachea, air sacs) or after growth in culture.

Mycoplasma isolates must be identified by species, because birds may also be infected with nonpathogenic mycoplasmas. *E coli* infection, Newcastle disease, avian influenza, and other respiratory diseases (eg, infectious bronchitis in chickens) should be considered in the differential diagnosis and can act as inciting or contributing pathogens.

Treatment, Control, and Prevention:

Most strains of *M gallisepticum* are sensitive to a number of broad-spectrum antibiotics, including tylosin, tetracyclines, and others but not to penicillins or those that act on the cell wall. Tylosin or tetracyclines have been commonly used to reduce egg transmission or as prophylactic treatment to prevent respiratory disease in broilers and turkeys. Antibiotics may alleviate the clinical signs and lesions but do not eliminate infection. Regulations on the use of

antibiotics in food animals are rapidly evolving and should be consulted before use.

Prevention is based largely on obtaining chicks or poults from *M gallisepticum*-free breeder flocks. Eradication of *M gallisepticum* from chicken and turkey commercial breeding stock is well advanced in the USA because of control programs coordinated by the National Poultry Improvement Plan. The most effective control program is to establish *M gallisepticum*-free breeder flocks, managed and maintained under good biosecurity to prevent introductions, and monitored regularly with serology to continually confirm infection-free status. In valuable breeding stock, treatment of eggs with antibiotics or heat has been used to eliminate egg transmission to progeny. Medication is not a good long-term control method but has been of value in treating individual infected flocks.

Laying chickens free of *M gallisepticum* are desirable, but infection in commercial multiple-age egg farms where depopulation is not feasible is a problem. Inactivated, oil-emulsion bacterins are available and help prevent egg production losses but not infection. Three live vaccines (F-strain, ts-11, and 6/85) have been licensed in the USA for use during the growing phase to provide some protection during lay and may be used in some areas with permission of the State Veterinarian. F-strain is of low virulence in chickens but is fully virulent for turkeys. Vaccinated chickens remain carriers of F-strain, and immunity lasts through the laying season. Vaccine strains ts-11 and 6/85 are less virulent, offer the advantage of improved safety for nontarget birds, and are widely used in commercial layers. A commercial recombinant fowlpox-*M gallisepticum* vaccine has been marketed.

MYCOPLASMA SYNOVIAE INFECTION

(Infectious synovitis)

M synoviae was first recognized as an acute to chronic infection of chickens and turkeys that produced an exudative tendinitis and synovitis (infectious synovitis); it now occurs most commonly as a subclinical infection of the upper respiratory tract, especially in multi-age layer flocks. *M synoviae* infection is also a complication of airsacculitis in association with Newcastle disease or infectious bronchitis. It is distributed worldwide and is seen primarily in chickens and turkeys, but ducks, geese, guinea fowl, parrots, pheasants, and quail may also be susceptible. Serum (preferably

swine) and nicotinamide adenine dinucleotide (NAD) are required for growth in mycoplasma media.

M synoviae isolates vary widely in virulence, and suspected virulence factors include adhesins, sialidase, nitric oxide, cell invasion, and antigenic variation and immune evasion.

Epidemiology and Transmission:

M synoviae is egg transmitted (transovarian), but the infection rate in breeder hens is low, and some hatches of progeny may be free of infection. Horizontal transmission is similar to that of *M gallisepticum* (see p 2841), primarily via the respiratory tract, with direct and indirect routes.

The incidence of *M synoviae* infection in commercial poultry in the USA has decreased because of the National Poultry Improvement Plan control programs implemented for chicken and turkey breeders. However, *M synoviae* infections of multiple-age layer flocks are common and may contribute to decreased egg production.

Clinical Findings and Lesions: Although slight rales may be present in birds with *M synoviae* respiratory infection, usually no signs are noticed. Birds under stress or with concurrent infections are more likely to be clinically affected. The first signs of infectious synovitis include pale-bluish head parts and lameness in many birds with a tendency to sit. The more severely affected birds are depressed and found resting around feeders and waterers. Hocks and footpads are swollen, and sternal bursitis (breast blisters) may be seen. Morbidity is usually low to moderate with mortality of 1%–10%. Effects on egg production are usually not apparent,

but instances of transient egg production drops have occurred in layer flocks.

Respiratory lesions may be absent, or consist of mild mucoid tracheitis or sinusitis with airsacculitis when birds are stressed from poor air quality or challenged with Newcastle disease or infectious bronchitis. Early in infectious synovitis, a creamy to viscous yellow-gray exudate is present in most synovial structures but most commonly seen in swollen hock and wing joints. In chronic cases, this exudate may become inspissated; livers are enlarged and sometimes green, spleens are enlarged, kidneys are enlarged and pale, and birds may be weak and thin with breast blisters from sternal recumbency.

Diagnosis: Skeletal abnormalities and trauma must be eliminated as the cause of lameness. Differential diagnoses include viral tenosynovitis as well as staphylococcal and other bacterial joint infections.

A presumptive diagnosis based on clinical signs and gross lesions should be confirmed by laboratory tests. Serum plate agglutination or ELISA are used to detect *M synoviae* antibodies, but cross-reactions with *M gallisepticum* and other nonspecific reactions may occur. These reactors are confirmed as seropositive by hemagglutination-inhibition or by culture, isolation, and identification of the organism. PCR may be used to rapidly detect *M synoviae* DNA from pre- or postmortem specimens. In turkeys, the agglutination test for *M synoviae* may not be reliable, especially in birds with predominantly respiratory infection.

Treatment, Control, and Prevention:

The National Poultry Improvement Plan coordinates control and serology-based surveillance programs for *M synoviae* similar to those for *M gallisepticum*. These programs have resulted in eradication of the infection in most primary breeder flocks of chickens and turkeys in the USA. Chicks and poults should be obtained from *M synoviae*-free breeders and raised with biosecurity to prevent introduction. Antibiotics in the feed may be beneficial in prevention of synovitis but are expensive and not very effective in established cases. When *M synoviae* involvement in airsacculitis is an anticipated problem, preventive antibiotic therapy during the time of respiratory reaction to Newcastle disease and infectious bronchitis vaccines may be helpful. A live temperature-sensitive vaccine (MS-H) is commercially available and permitted in some areas.

MYCOPLASMA MELEAGRIDIS INFECTION

M meleagridis causes an egg-transmitted (transovarian) disease of breeder turkeys that primarily impacts progeny with airsacculitis but has also been associated with decreased hatchability from infected breeder flocks and with poor growth and skeletal abnormalities in progeny.

M meleagridis is strongly host-specific for turkeys (not for chickens), and with successful control programs (National Poultry Improvement Plan in the USA) major turkey primary breeders have eliminated the infection from their stocks, producing eggs and poults free of *M meleagridis*.

Epidemiology and Transmission:

Before control programs, turkeys worldwide were commonly infected with *M meleagridis*. Infection of progeny occurs primarily through vertical (egg) transmission with rates that vary over the laying season. At the hatchery, organisms may be spread horizontally via aerosols from the respiratory tract or to the vent on contaminated hands during vent-sexing. Respiratory tract infection also leads to horizontal transmission among birds within young growing flocks and may be a factor in the spread to flocks previously free of infection (flock-to-flock transmission). In some infected turkeys, organisms localize in the reproductive tract; thus, the source of vertical transmission in hens is organisms incorporated in eggs. In toms, the phallus and adjacent tissues (cloaca) become infected and contaminate the semen. Artificial insemination of turkey hens with infected semen is an additional important method of transmission. Additionally, indirect transmission may result from management practices such as vaccination, whereby mycoplasmas are carried manually from infected to noninfected turkeys via contaminated hands, clothing, and equipment.

The marked difference in the pathogenicity of various strains of *M meleagridis* results in variable clinical manifestations, with airsacculitis in poults being the most common. High prevalence of airsacculitis with low mortality in poults suggests a highly evolved host-parasite relationship.

Clinical Findings and Lesions: Egg transmission and embryo infection reduces hatchability (due to late embryo mortality), poult quality, and growth rate. Only mild

respiratory signs may be seen despite high rates of airsacculitis in poult s from infected hens. Egg-borne infections may impact early rapid growth of hock joints, periarticular tissues, cervical vertebrae, and adjacent bone, producing skeletal abnormalities such as crooked (wry) necks or leg deformities. Adult breeders usually show no signs of venereal or respiratory infection.

Hatched poult s may have airsacculitis with variable degrees of thickening, turbidity, foamy yellow exudate, and caseous flecks. These lesions recede with age. Poult s with wry neck may have cervical airsacculitis and osteomyelitis of adjacent vertebrae. The generalized skeletal lesions that may develop in poult s 1–6 wk old are characterized by chondrodystrophy or by varus deformities and perosis.

Microscopic lesions in hens consist of lymphocytic foci in the fimbria, uterus, and vagina, with plasma cells and heterophils in the lamina propria of the reproductive tract. Infected embryos and young poult s show inflammatory lesions of pneumonia and exudative airsacculitis.

Diagnosis: A high prevalence of airsacculitis in day-old poult s suggests *M meleagridis* infection. Serology by agglutination (tube or plate) or ELISA can demonstrate antibody. Confirmation was generally by hemagglutination-inhibition serology or by culture, isolation, and identification of the organism. PCR is now used to detect *M meleagridis* DNA from pre- or postmortem specimens. *M gallisepticum*, other *Mycoplasma* spp, and mixed infections (polymicrobial disease) must be considered in the differential diagnosis.

Treatment, Control, and Prevention:

Turkey eggs or poult s should be obtained from breeder flocks free of *M meleagridis* and monitored by serology and/or by examining pipped embryos or cull poult s for airsacculitis. Semen used for insemination must be free of *M meleagridis*. Dipping eggs in tylosin or other antibiotic reduces the incidence of transmission in infected flocks. However, this practice has been generally eliminated with the eradication of *M meleagridis* from primary breeder flocks and is only used by multiplier breeders when there is an outbreak. Injection of a suitable antibiotic at 1 day of age or water medication for the first 5–10 days appeared to reduce infection and airsacculitis caused by *M meleagridis* and improve weight gain.

MYCOPLASMA IOWAE INFECTION

M iowae infection of turkey breeder hens has been most commonly associated with late embryo mortality and reduced hatchability and occasionally with a low prevalence of leg abnormalities in their young progeny. *M iowae* requires enriched media with cholesterol, similar to those used for other avian mycoplasmas for culture and isolation, but is resistant to bile salts.

Epidemiology and Transmission:

M iowae is egg transmitted (transovarian) in turkeys, and horizontal transmission with slow spread within a flock may occur. Antigenicity and virulence vary considerably among *M iowae* strains. Infection rates in turkey flocks in Europe and North America have been reduced by intensive eradication efforts in certain primary breeding stocks, but *M iowae* is not currently included in the National Poultry Improvement Plan. It is a relatively uncommon infection of chickens and has been reported in geese.

Chickens and turkeys experimentally inoculated have shown airsacculitis, stunting, poor feathering, and leg lesions. These effects are rarely recognized in the field, except for some outbreaks in young turkeys with skeletal lesions.

Clinical Findings and Lesions: Affected turkey breeder flocks show no clinical signs other than reduced hatchability (usually

Mycoplasma iowae infection, turkeys. (A) Normal vs chondrodystrophic legs (left) of 28-day-old turkeys; note short, thick shanks and toes. (B) Legs of a 42-day-old turkey showing bilateral chondrodystrophy; note short, thick legs with enlarged hocks and marked medial bowing of both legs. Courtesy of North Carolina State University Poultry Health Management.

2%–5%) due to embryo mortality in the last 10 days of incubation. In many flocks, the hatchability returns to normal after 1–2 mo.

Dead turkey embryos are edematous, congested, and stunted; they may have “clubbed down.” Poults experimentally challenged in ovo or at 1 day of age developed various skeletal deformities such as rotated tibia, deviated toes, chondrodystrophy, or erosion of the articular cartilage of the hock joint. Chicks experimentally challenged at 1 day of age developed tenosynovitis and ruptured tendons.

Natural infections in several young commercial turkey flocks were associated with skeletal lesions consistent with chondrodystrophy, characterized by leg and vertebral deformities. Microscopic skeletal lesions were characterized by excess cartilage matrix and disorganization of chondrocytes, features of osteochondrosis.

Diagnosis: In turkeys, *M. iowae* infection should be considered in cases of late embryo mortality and decreased hatchability and in young turkeys with leg and vertebral chondrodystrophy. *M. meleagridis* and nutrient deficiencies are the top differential diagnoses for these conditions, respectively.

Turkeys develop only a weak antibody response to *M. iowae*, and no reliable serologic test is available. Diagnosis relies on culture, isolation, and identification of the organism, or on detection of *M. iowae* DNA by PCR.

Treatment, Control, and Prevention:

The best method of control and prevention is to establish and maintain turkey breeder flocks free of *M. iowae*. Surveillance is challenging because serology is unreliable, but flock monitoring by PCR and strict biosecurity should help.

MYCOTOXICOSES

A mycotoxicosis is a disease caused by a natural toxin produced by a fungus. In poultry, this usually results when toxin-producing fungi grow in grain and feed. Hundreds of mycotoxins have been identified, and many are pathogenic. Mycotoxins may have additive or synergistic effects with other natural toxins, infectious agents, and nutritional deficiencies. Many are chemically stable and maintain toxicity over time. (See also MYCOTOXICOSES, p 3005.)

The significance of mycotoxin problems in poultry is probably considerable but yet insidious. The impact on poultry production may be best measured indirectly by the improvements in weight gain, feed efficiency, pigmentation, egg production, and reproductive performance that accompany effective control programs for mycotoxins.

Aflatoxicosis: The aflatoxins are toxic and carcinogenic metabolites of *Aspergillus flavus*, *A. parasiticus*, and others. Aflatoxicosis in poultry primarily affects the liver but can involve immunologic, digestive, and hematopoietic functions. Aflatoxin can adversely affect weight gain, feed intake, feed conversion efficiency, pigmentation, processing yield, egg production, male and female fertility, and

hatchability. Some effects are directly attributable to toxins, whereas others are indirect, such as reduced feed intake. Susceptibility to aflatoxins varies, but in general, ducklings, turkeys, and pheasants are susceptible, while chickens, Japanese quail, and guinea fowl are relatively resistant.

Clinical signs vary from general unthriftiness to high morbidity and mortality. At necropsy the lesions are found mainly in the liver, which can be reddened due to necrosis and congestion or yellow due to lipid accumulation. Hemorrhages may occur in liver and other tissues. In chronic aflatoxicosis, the liver becomes yellow to gray and atrophied. The aflatoxins are carcinogenic, but tumor formation is rare with the natural disease, probably because the birds do not live long enough for this to occur.

Fusariotoxosis: The genus *Fusarium* produces many mycotoxins injurious to poultry. The trichothecene mycotoxins produce caustic and radiomimetic patterns of disease exemplified by T-2 toxin and diacetoxyscirpenol (DAS). Deoxynivalenol (vomitoxin, DON) and zearalenone are common trichothecene mycotoxins that are relatively nontoxic for poultry but may cause disease in pigs.

Fusariotoxycosis in poultry caused by the trichothecenes results in feed refusal, caustic injury of the oral mucosa and areas of the skin in contact with the mold, acute digestive disease, and injury to the bone marrow and immune system. Lesions include necrosis and ulceration of the oral mucosa, reddening of the GI mucosa, mottling of the liver, atrophy of the spleen and other lymphoid organs, and visceral hemorrhages. In laying hens, decreased egg production can be accompanied by depression, recumbency, feed refusal, and cyanosis evident in the comb and wattles. Ducks and geese develop necrosis and pseudomembranous inflammation of the esophagus, proventriculus, and gizzard.

Other *Fusarium* mycotoxins cause defective growth of long bones. The fumonisin mycotoxins produced by *F. verticillioides* (formerly *F. moniliforme*) impair feed conversion without causing specific lesions. Moniliformin is also produced by *F. verticillioides* and is cardiotoxic and nephrotoxic in poultry. *F. verticillioides* causes ear rot, kernel rot, and stalk rot of unharvested corn and is found in stored high-moisture shelled corn and on other grains that appear sound.

Ochratoxycosis: Ochratoxins are quite toxic to poultry. These nephrotoxins are produced chiefly by *Penicillium viridicatum* and *Aspergillus ochraceus* in grains and feed. Ochratoxycosis causes primarily renal disease but also affects the liver, immune system, and bone marrow. Severe intoxication causes reduced spontaneous activity, huddling, hypothermia, diarrhea, rapid weight loss, and death. Moderate intoxication impairs weight gain, feed conversion, pigmentation, carcass yield, egg production, fertility, and hatchability.

Ergotism: Toxic ergot alkaloids are produced by *Claviceps* spp, which are fungi that attack cereal grains. Rye is especially affected, but also wheat and other leading cereal grains. The mycotoxins form in the sclerotium, a visible, hard, dark mass of mycelium that displaces the grain tissue. Within the sclerotium are the ergot alkaloids, which affect the nervous system, causing convulsive and sensory neurologic disorders; the vascular system, causing vasoconstriction and gangrene of the extremities; and the endocrine system, including neuroendocrine control of the anterior pituitary gland.

In chicks, the toes become discolored due to vasoconstriction and ischemia. In older birds, vasoconstriction affects the comb, wattles, face, and eyelids, which become

atrophied and disfigured. Vesicles and ulcers develop on the shanks of the legs and on the tops and sides of the toes. In laying hens, feed consumption and egg production are reduced.

Citrinin Mycotoxycosis: Citrinin is produced by *Penicillium* and *Aspergillus* spp and is a natural contaminant of corn, rice, and other cereal grains. Citrinin causes a diuresis that results in watery fecal droppings and reductions in weight gain. At necropsy, lesions are generally mild and involve the kidney.

Oosporein Mycotoxycosis: Oosporein is a mycotoxin produced by *Chaetomium* spp that causes gout and high mortality in poultry. *Chaetomium* are found on feeds and grains, including peanuts, rice, and corn. Oosporein mycotoxycosis is seen as visceral and articular gout related to impaired renal function and increased plasma concentrations of uric acid. Chickens are more sensitive to oosporein than turkeys. Water consumption increases during intoxication, and fecal droppings become unformed and fluid.

Cyclopiazonic Acid: Cyclopiazonic acid is a metabolite of *Aspergillus flavus*, which is the predominant producer of aflatoxin in feeds and grains. In chickens, cyclopiazonic acid causes impaired feed conversion, decreased weight gain, and mortality. Lesions develop in the proventriculus, gizzard, liver, and spleen. The proventriculus is dilated, and the mucosa is thickened and sometimes ulcerated.

Sterigmatocystin: Sterigmatocystin, a biogenic precursor to aflatoxin, is hepatotoxic and hepatocarcinogenic but is less common than aflatoxin.

Diagnosis: Mycotoxycosis should be suspected when the history, signs, and lesions are suggestive of feed intoxication, and especially when moldy ingredients or feed are evident. Toxin exposure associated with consumption of a new batch of feed may result in subclinical or transient disease. Chronic or intermittent exposure can occur in regions where grain and feed ingredients are of poor quality or when feed storage is substandard or prolonged. Impaired production can be a clue to a mycotoxin problem, as can improvement because of correction of feed management deficiencies.

Definitive diagnosis involves detection and quantitation of the specific toxin(s). This can be difficult because of the rapid and high-volume use of feed and ingredients

in poultry operations. Diagnostic laboratories differ in their respective capabilities to test for mycotoxins and should be contacted before sending samples. Feed and also birds that are sick or recently dead should be submitted for testing. A necropsy and related diagnostic tests should accompany feed analysis if mycotoxicosis is suspected. Concurrent diseases can adversely affect production and should be considered. Sometimes, a mycotoxicosis is suspected but not confirmed by feed analysis. In these situations, a complete laboratory evaluation can exclude other significant diseases.

Feed and ingredient samples should be properly collected and promptly submitted for analysis. Mycotoxin formation can be localized in a batch of feed or grain. Multiple samples taken from different sites increase the likelihood of confirming a mycotoxin formation zone (hot spot).

Samples should be collected at sites of ingredient storage, feed manufacture and transport, feed bins, and feeders. Fungal activity increases as feed is moved from the feed mill to the feeder pans. Samples of 500 g (1 lb) should be collected and submitted in separate containers. Clean paper bags, properly labeled, are adequate. Sealed plastic or glass containers are appropriate only for short-term storage and transport, because feed and grain rapidly deteriorate in airtight containers.

Treatment: The toxic feed should be removed and replaced with unadulterated feed. Concurrent diseases should be treated to alleviate disease interactions, and substandard management practices must be corrected. Some mycotoxins increase requirements for vitamins, trace minerals (especially selenium), protein, and lipids and can be compensated for by feed supplementation and water-based treatment. Nonspecific toxicologic therapies using activated charcoal (digestive tract adsorption) in the feed

have a sparing effect but are not practical for large production units.

Prevention: Prevention of mycotoxicoses should focus on using feed and ingredients free of mycotoxins and on management practices that prevent mold growth and mycotoxin formation during feed transport and storage. Regular inspection of feed storage and feeding systems can identify flow problems, which allow residual feed and enhance fungal activity and mycotoxin formation. Mycotoxins can form in decayed, crusted feed in feeders, feed mills, and storage bins; cleaning and correcting the problem can have immediate benefits. Temperature extremes cause moisture condensation and migration in bins and promote mycotoxin formation.

Ventilation of poultry houses to avoid high relative humidity also decreases the moisture available for fungal growth and toxin formation in the feed. Antifungal agents added to feeds to prevent fungal growth have no effect on toxin already formed but may be cost-effective in conjunction with other feed management practices. Organic acids (propionic acid, 500–1,500 ppm [0.5–1.5 g/kg]) are effective inhibitors, but the effectiveness may be reduced by the particle size of feed ingredients and the buffering effect of certain ingredients. Sorbent compounds such as hydrated sodium calcium aluminosilicate (HSCAS) effectively bind and prevent absorption of aflatoxin. Esterified glucomannan, derived from the cell wall of the yeast *Saccharomyces cerevisiae*, is protective against aflatoxin B₁ and ochratoxins. It reduces toxicity through the binding and reduction in bioavailability of fumonisins, zearalenone, and T-2 toxin. Various other fermentation products, algae and plant extracts, and microbial feed additives have demonstrated ability to bind or degrade mycotoxins and may be applicable and appropriate for the situation.

NEOPLASMS

Depending on whether the etiologic agent is known, neoplasms of poultry are divided into two main categories: virus-induced neoplasms and neoplasms of unknown etiology. There are three economically important virus-induced neoplastic diseases

of poultry: Marek's disease, caused by a herpesvirus, and avian leukosis/sarcoma and reticuloendotheliosis, caused by retroviruses. While these neoplastic diseases cause economic losses from tumor mortality and poor performance, some of

them have served as highly suitable models to study neoplasia.

A rare neoplastic disease of turkeys known as lymphoproliferative disease that has been reported in Europe and Israel is induced by a retrovirus that is distinct from both the leukosis/sarcoma and reticuloendotheliosis viruses. Although reports suggest that lymphoproliferative disease has recently been detected by PCR in a small number of wild turkeys in the USA, incidence of the disease has always been sporadic and therefore is not discussed in this chapter.

Neoplasms of unknown etiology are classified according to their morphologic characteristics; they include a wide variety of benign and malignant neoplasms. Of these tumors, only dermal squamous cell carcinoma (avian keratoacanthoma), multicentric histiocytosis, and adenocarcinoma are discussed in this chapter.

MAREK'S DISEASE

Chickens are the most important natural host for Marek's disease virus, a highly cell-associated but readily transmitted alphaherpesvirus with lymphotropic properties of gammaherpesviruses. Quail can be naturally infected, and turkeys can be infected experimentally. However, severe clinical outbreaks of Marek's disease in commercial turkey flocks, with mortality from tumors reaching 40%–80% between 8 and 17 wk of age, were reported in France, Israel, and Germany. In some of these cases, the affected turkey flocks were raised in proximity to broilers. Turkeys are also commonly infected with turkey herpesvirus (HVT), an avirulent strain related to Marek's disease virus that is commonly used as a Marek's disease vaccine in chickens. Other birds and mammals appear to be refractory to the disease or infection.

Marek's disease is one of the most ubiquitous avian infections; it is identified in chicken flocks worldwide. Every flock, except for those maintained under strict pathogen-free conditions, is presumed to be infected. Although clinical disease is not always apparent in infected flocks, a subclinical decrease in growth rate and egg production may be economically important.

Etiology: Marek's disease virus is a member of the genus *Mardivirus* within the subfamily Alphaherpesvirinae. Within the genus *Mardivirus* are three closely related species previously designated as three serotypes of Marek's disease virus. Gallid herpesvirus 2 (MDV-1) represents all

virulent Marek's disease virus strains and is further divided into pathotypes, designated as mild (m), virulent (v), very virulent (vv), and very virulent plus (vv+). Gallid herpesvirus 3 (MDV-2) and Meleagrid herpesvirus 1 (turkey herpesvirus, MDV-3) represent avirulent virus strains isolated from chickens and turkeys, respectively, and are commonly used as vaccines against Marek's disease.

Transmission and Epidemiology:

The disease is highly contagious and readily transmitted among chickens. The virus matures into a fully infective, enveloped form in the epithelium of the feather follicle, from which it is released into the environment. It may survive for months in poultry house litter or dust. Dust or dander from infected chickens is particularly effective in transmission. Once the virus is introduced into a chicken flock, regardless of vaccination status, infection spreads quickly from bird to bird. Infected chickens continue to be carriers for long periods and act as sources of infectious virus. Shedding of infectious virus can be reduced, but not prevented, by prior vaccination. Unlike virulent strains of Marek's disease virus, which are highly contagious, turkey herpesvirus is not readily transmissible among chickens (although it is easily transmitted among turkeys, its natural host). Attenuated Marek's disease virus strains vary greatly in their transmissibility among chickens; the most highly attenuated are not transmitted. Marek's disease virus is not vertically transmitted.

Pathogenesis: Currently, four phases of infection *in vivo* are recognized: 1) early productive-restrictive virus infection causing primarily degenerative changes, 2) latent infection, 3) a second phase of cytolytic, productive-restrictive infection coincident with permanent immunosuppression, and 4) a proliferative phase involving nonproductively infected lymphoid cells that may or may not progress to the point of lymphoma formation. Productive infection may occur transiently in B lymphocytes within a few days after infection with virulent Marek's disease virus strains and is characterized by antigen production, which leads to cell death. Because few if any virions are produced, this has also been termed a restrictive-productive infection. Productive infection also occurs in the feather follicle epithelium, in which enveloped virions are produced. Latent infection of activated T cells is responsible for the longterm

carrier state. No antigens are expressed, but virus can be recovered from such lymphocytes by co-cultivation with susceptible cells in tissue cultures. Some T cells, latently infected with oncogenic Marek's disease virus strains, undergo neoplastic transformation. These transformed cells, provided they escape the immune system of the host, may multiply to form characteristic lymphoid neoplasms. Cell-mediated and humoral immune responses are both directed against viral antigens, with cell-mediated immunity probably being the most important.

Clinical Findings: The incidence of Marek's disease is quite variable in commercial flocks and depends on strain and dose of virus, age at exposure, maternal antibody, host gender and genetics, strain and dose of vaccine virus, and several environmental factors, including stress. In addition to lymphoid neoplasms, Marek's disease virus can also induce other clinically distinct disease syndromes, including transient paralysis, early mortality syndrome, cytolytic infection, atherosclerosis, and persistent neurologic disease. Typically, affected birds show only depression before death, but a transient paralysis syndrome has been associated with Marek's disease; chickens become ataxic for periods of several days and then recover. This syndrome is rare in immunized birds. Death is usually the result of paralysis, rendering the birds unable to reach food and water.

Lesions: Enlarged nerves are one of the most consistent gross lesions in affected birds. Various peripheral nerves, but particularly the vagus, brachial, and sciatic, become enlarged and lose their striations. Diffuse or nodular lymphoid tumors may be seen in various organs, particularly the liver, spleen, gonads, heart, lung, kidney, muscle, and proventriculus. Enlarged feather

follicles (commonly termed skin leukosis) may be noted in broilers after defeathering during processing and are a cause for condemnation. The bursa is only rarely tumorous and more frequently is atrophic. Histologically, the lesions consist of a mixed population of small, medium, and large lymphoid cells plus plasma cells and large anaplastic lymphoblasts. These cell populations undoubtedly include tumor cells and reactive inflammatory cells. When the bursa is involved, the tumor cells typically appear in interfollicular areas.

Diagnosis: For the diagnosis of Marek's disease, it is critical to diagnose the tumors and not the infection because Marek's disease is considered ubiquitous within commercial poultry flocks. Usually, diagnosis is based on enlarged nerves and lymphoid tumors in various viscera. The absence of bursal tumors helps distinguish this disease from lymphoid leukosis (see below), although the presence of bursal tumors does not exclude Marek's disease. Marek's disease can develop in chickens as young as 3 wk old, whereas lymphoid leukosis typically is seen in chickens > 14 wk old. Reticuloendotheliosis, although rare, can easily be confused with Marek's disease, because both diseases feature enlarged nerves and T-cell lymphomas in visceral organs. A diagnosis based on typical gross lesions may be confirmed histologically, or preferably by demonstration of predominant T-cell populations and Marek's viral DNA in lymphomas by histochemistry and PCR, respectively. There is a quantitative association between viral load and Marek's disease tumors; most tumor-bearing chickens have high viremia titers and are usually PCR positive. Thus, the demonstration of high quantities of virus, viral DNA, or viral antigens in tumor cells and the exclusion of other relevant tumor viruses should be sufficient for a specific diagnosis of Marek's disease. Furthermore, Marek's disease lymphomas usually lack evidence of clonally integrated avian retroviruses or alteration of the cellular oncogene *c-myc*.

Control: Vaccination is the central strategy for the prevention and control of Marek's disease. The efficacy of vaccines can be improved, however, by strict sanitation to reduce or delay exposure and by breeding for genetic resistance. Probably the most widely used vaccine consists of turkey herpesvirus (HVT), which has seen rapidly increased use as a backbone in recombinant vaccines featuring the insertion of genes from other poultry

Typical presentation of leg paresis in a chicken with Marek's disease. Courtesy of Dr. Jean Sander.

viruses, such as Newcastle disease virus (see p 2856), infectious bursal disease virus (see p 2837), or infectious laryngotracheitis virus (see p 2912). These recombinant vaccines offer protection against both Marek's disease virus and the inserted virus. Bivalent vaccines consisting of HVT and either the SB-1 or 301B/1 strains of Gallid herpesvirus 3 have been used to provide additional protection against challenge with virulent Marek's disease virus isolates. The most protective commercial vaccine currently available appears to be CVI988/Rispens, an attenuated Marek's disease virus strain that is also commonly mixed with HVT at vaccination. Because vaccines are administered at hatching and require 1–2 wk to produce an effective immunity, exposure of chickens to virus should be minimized during the first few days after hatching.

Vaccines are also effective when administered to embryos at the 18th day of incubation. In ovo vaccination is now performed by automated technology and is widely used for vaccination of commercial broiler chickens, mainly because of reduced labor costs and greater precision of vaccine administration.

Proper handling of vaccine during thawing and reconstitution is crucial to ensure that adequate doses are administered. Cell-associated vaccines are generally more effective than cell-free vaccines, because they are neutralized less by maternal antibodies. Under typical conditions, vaccine efficacy is usually >90%. Since the advent of vaccination, losses from Marek's disease have been reduced dramatically in broiler and layer flocks. However, disease may become a serious problem in individual flocks or in selected geographic areas (eg, the Delmarva broiler industry). Of the many causes proposed for these excessive losses, early exposure to very virulent virus strains appears to be among the most important.

LYMPHOID LEUKOSIS

(Avian leukosis)

Under natural conditions, lymphoid leukosis has been the most common form of the leukosis/sarcoma group of diseases seen in chicken flocks, although in the 1990s myeloid leukosis become prevalent in meat-type chickens. The International Committee on Taxonomy of Viruses placed viruses of the avian leukosis/sarcoma group in the *Alpharetrovirus* genus of the family Retroviridae.

Members of this RNA group of viruses have similar physical and molecular characteristics and share a common group-specific antigen. Detection of the major antigen (p27) present in the core of leukosis/sarcoma viruses forms the basis of several diagnostic tests. Lymphoid leukosis occurs naturally only in chickens. Experimentally, some of the viruses of the leukosis/sarcoma group can infect and produce tumors in other species of birds or even mammals. The infection is known to exist in virtually all chicken flocks except for some SPF flocks from which it has been eradicated. Tumor mortality commonly accounts for ~1%–2% of birds, with occasional losses of ≥20%. Subclinical infection, to which most flocks are subject, decreases several important performance traits, including egg production and quality. The frequency of infection has been reduced substantially in the primary breeding stocks of several commercial poultry breeding companies, particularly egg-type breeders. In recent years this control program has expanded, and infection has become infrequent or absent in certain commercial flocks. The frequency of lymphoid leukosis tumors even in heavily infected flocks is typically low (<4%), and disease is often inapparent. As much as 1.5% excess mortality per wk has been reported in commercial broiler-breeder flocks naturally infected with subgroup J avian leukosis virus.

Etiology: Lymphoid leukosis is caused by certain members of the leukosis/sarcoma group of avian retroviruses. Isolates that can induce lymphoid leukosis in chickens are commonly called avian leukosis viruses and are divided into subgroups A, B, C, D, and J, on the basis of differences in their viral envelope glycoproteins, which determine antigenicity, viral interference patterns with members of the same and different subgroups, and host range. Subgroups A and B are most prevalent in western countries. Since the initial isolation of subgroup J avian leukosis virus in England, the virus has been isolated from broiler-breeder stocks that experience myeloid neoplasms (myelocytoma) in many other countries. A sixth subgroup (E) designates nononcogenic endogenous viruses produced by viral genes integrated into the host cell DNA. All field strains of avian leukosis virus are oncogenic, although some differences in oncogenicity and replicative ability have been recognized. Recently, recombinant avian leukosis viruses with the envelope of subgroup B and long terminal repeat of subgroup J have been isolated from field cases of myeloid

leukosis in commercial layers. Another recombinant avian leukosis virus with the envelope of subgroup A and long terminal repeat of subgroup E was shown to be a contaminant in commercial Marek's disease vaccines. Thus, recombination between two different subgroups of avian leukosis virus can occur in field conditions and cause economic losses.

Transmission and Epidemiology:

Chickens are the natural hosts for all viruses of the leukosis/sarcoma group; these viruses have not been isolated from other avian species except pheasants, partridges, and quail. Avian leukosis virus is shed by the hen into the albumen or yolk, or both; infection probably occurs after the onset of incubation. Congenitally infected chickens fail to produce neutralizing antibodies and usually remain viremic for life. Horizontal infection after hatching is also important, especially when chicks are exposed immediately after hatching to high doses of virus, eg, in feces of congenitally infected chicks or in contaminated vaccines. Horizontally infected chickens have a transient viremia followed by antibody production. The earlier the infection, the more likely it is to lead to tolerance, persistent viremia, and tumors. Other factors known to increase the susceptibility of chickens to horizontal infection include the absence of maternal antibodies and the presence of endogenous retroviruses, especially those associated with the late feathering (K) gene. Tumors are more frequent in congenital than in horizontal infections, but many more chickens are exposed horizontally than congenitally. Rates of embryo transmission typically are 1%–10%; virtually all chicks in an infected flock are exposed by contact. Congenital and, in some cases, early horizontal infection can induce permanent carrier states characterized by shedding of virus or antigen into the environment and into eggs. Late infection (ie, inoculation at 12–20 wk of age) is unlikely to lead to viral shedding.

Four classes of avian leukosis virus infection are recognized in mature chickens: (1) no viremia, no antibody (V-A-); (2) no viremia, with antibody (V-A+); (3) with viremia, with antibody (V+A+); and (4) with viremia, no antibody (V+A-). Birds in an infection-free flock and genetically resistant birds in a susceptible flock fall into the category V-A-. Genetically susceptible birds in an infected flock fall into one of the other three categories. Most are V-A+, and a minority, usually <10%, are V+A-. Most V+A-hens transmit the virus to a varying but relatively high proportion of their progeny.

The virus is not highly contagious compared with other viral agents and is readily inactivated by disinfectants. Transmission can be reduced or eliminated by strict sanitation. After the infection is eradicated, standard disease control and sanitation practices can keep chicken flocks free of the disease. The role of males in transmission of avian leukosis virus is uncertain. Infected cocks apparently do not influence the rate of congenital infection of progeny but act only as virus carriers and sources of contact or venereal infection to other birds.

Pathogenesis: Lymphoid leukosis is a clonal malignancy of the bursal-dependent lymphoid system. Transformation invariably occurs in the intact bursa, often as early as 4–8 wk after infection. Tumors are often not detectable until ~14 wk of age. Death rarely occurs before 14 wk of age and is more frequent around the time of sexual maturity. The disease can be prevented, even up to 5 mo of age, by treatments that destroy the bursa. The tumors are composed almost entirely of B lymphocytes that, in many instances, have IgM on their surfaces. No antitumor immune response has been recognized. Antibodies are readily induced after infection, except when tolerance occurs.

The induction of lymphoid leukosis tumors can be enhanced in chickens coinfecting with serotype 2 Marek's disease virus, a common vaccine virus. This enhancement requires a genetically susceptible chicken and early infection with lymphoid leukosis virus in addition to serotype 2 Marek's disease vaccination. Because most commercial chicken strains are resistant, and lymphoid leukosis virus infection has been largely eradicated from susceptible stocks, enhancement is not currently recognized as a field problem.

A subclinical disease syndrome characterized by depressed egg production in the absence of tumor formation is more important economically than are deaths from lymphoid leukosis. Chickens with subclinical disease usually shed virus or viral antigen into the albumen of eggs. The pathogenic mechanisms are poorly understood.

Clinical Findings and Lesions: Chickens with lymphoid leukosis have few typical clinical signs. These may include inappetence, weakness, diarrhea, dehydration, and emaciation. Infected chickens become depressed before death. Palpation often reveals an enlarged bursa and sometimes an enlarged liver. Infected birds may not necessarily develop tumors, but they may lay fewer eggs.

Diffuse or nodular lymphoid tumors are common in the liver, spleen, and bursa and are found occasionally in the kidneys, gonads, and mesentery. Involvement of the bursa has been considered virtually pathognomonic, although bursal lymphomas are also known to be induced by reticuloendotheliosis virus. Sometimes the bursal tumors are small and seen only after careful examination of the mucosal surface of the organ. Usually, no enlargement of peripheral nerves is apparent, although such lesions have been noted after experimental inoculation of subgroup J virus. Microscopically, the tumor cells are uniform, large lymphoblasts. Mitotic figures are frequent.

Outbreaks of neoplasms other than lymphoid leukosis such as myelocytomas, hemangiomas, and renal tumors have also been noted in meat-type chickens infected with subgroup J avian leukosis virus. Myelocytomatosis and skeletal myelocytomas may cause protuberances on the head, thorax, and shanks. Myelocytomas may occur in the orbit of the eye, causing hemorrhage and blindness. Hemangiomas may occur in the skin, appearing as "blood blisters," which may rupture and bleed. Renal tumors may cause paralysis due to pressure on the sciatic nerve. Microscopically, in cases of myelocytomas induced by subgroup J avian leukosis virus, the liver shows a massive intravascular and extravascular accumulation of myeloblasts characterized by the presence of cytoplasmic eosinophilic granules.

Most strains of leukosis/sarcoma viruses also induce nonlymphoid tumors (including sarcomas), erythroblastosis, myeloblastosis, myelocytomas, hemangiomas, nephroblastomas, osteopetrosis, and related neoplasms. The nature of the tumors and their frequency depend on virus strain, chicken strain, age, dose, and route of infection. Occasional outbreaks of predominantly one type of tumor are seen in the field. The Rous sarcoma virus, a member of this group, has been widely studied in the laboratory. Each strain usually causes a predominantly neoplastic disease and can be distinguished on the basis of pathogenicity. Some viruses (eg, Rous sarcoma and erythroblastosis viruses) contain a viral oncogene that enables the virus to induce neoplasms within a short incubation period, but such viruses are rare in the field. Others cannot replicate on their own and require a nondefective helper virus. In recent years, avian leukosis virus infection has been shown to be associated with the so-called "fowl glioma," characterized by cerebellar hypoplasia and myocarditis.

Diagnosis: Because avian leukosis virus is widespread among chickens, virus detection tests, including virus isolation and PCR and the demonstration of antigen or antibody, have limited or no value in diagnosing field cases of lymphomas. Gross characteristics of diagnostic significance include the tumorous involvement of the liver, spleen, or bursa in the absence of peripheral nerve lesions. The tumors are found in birds >14 wk old. Histologically, the lymphoid cells are uniform in character, large, and contain IgM and B-cell markers on their surface. Tumors can be differentiated from those of Marek's disease by gross and microscopic pathology and by molecular techniques that demonstrate the characteristic clonal integration of proviral DNA into the tumor cell genome with the associated disruption of the *c-myc* oncogene. Lymphoid leukosis cannot easily be differentiated from B-cell lymphomas caused by reticuloendotheliosis virus except by virologic assays; however, such tumors probably are extremely rare. Several PCR primers specific for detection of the most commonly isolated avian leukosis viruses, particularly subgroups A and J, have been developed. Other primers specific for endogenous, subgroup E avian leukosis virus have also been used. PCR has been used to detect and characterize avian leukosis virus strains contaminating commercial live virus vaccines of poultry. ELISA kits for detection of antibodies to avian leukosis virus subgroups A, B, and J are available commercially.

Control: Eradication of avian leukosis virus from primary breeding stocks is the most effective means to control avian leukosis virus infection and lymphoid leukosis in chickens. Breeder flocks are evaluated for viral shedding by testing for viral antigens in the albumen of eggs with enzyme immunoassays or by biologic assays for infectious virus. Eggs from shedder hens are discarded, so that progeny flocks typically have reduced levels of infection. If raised in small groups, infection-free flocks can be derived with relative ease. These control measures are applied only to primary breeder flocks. Voluntary programs to reduce viral infection have already reduced mortality from lymphoid leukosis and improved egg production in most layer strains; similar programs were equally successful in certain meat strains. Some breeders favor, and have virtually achieved, total eradication, while others favor a reduced level of viral infection. Some chickens have specific genetic resistance to

infection with certain subgroups of virus. Although genetic cellular resistance is unlikely to replace the need for reduction or eradication of the virus, the cellular receptor gene has recently been cloned, and quick molecular assays for viral susceptibility could be developed. Thus far, vaccination for tumor prevention has not been promising.

RETICULOENDOTHELIOSIS

Reticuloendotheliosis designates a group of neoplastic and immunosuppressive syndromes in several avian species caused by reticuloendotheliosis virus, a member of the avian retrovirus group. The host range of reticuloendotheliosis virus is much broader than that of Marek's disease or avian leukosis. Natural infection and disease occurs in chickens, turkeys, ducks, geese, and quail; probably many species of birds can be infected. Mammals appear refractory, although certain mammalian cell cultures are susceptible.

Reticuloendotheliosis virus is not as ubiquitous as Marek's disease and avian leukosis viruses but is more widely distributed than once believed. Many recent cases have been attributed to accidental contamination of live virus poultry vaccines such as Marek's disease virus and fowlpox virus with reticuloendotheliosis virus. Although clinical outbreaks are not frequently seen, serologic surveys suggest that the virus is prevalent in both chicken and turkey flocks in many countries, including the USA.

Etiology: Reticuloendotheliosis virus is immunologically, morphologically, and structurally distinct from the leukosis/sarcoma group of avian retroviruses. The International Committee on Taxonomy of Viruses has classified reticuloendotheliosis viruses within the family Retroviridae, subfamily Orthoretrovirinae, genus *Gammaretrovirus*. Although all isolates belong to a single serotype, three subtypes of reticuloendotheliosis virus have been identified on the basis of neutralization tests and differential reactivity with monoclonal antibodies. Strains can be further classified by their ability to replicate in cell culture. Most field isolates appear to be nondefective for replication in cell cultures and contain no viral oncogene. One unique laboratory strain (strain T) is defective for replication in cell cultures and contains a viral oncogene, *v-rel*, that is responsible for an acute reticulum cell neoplasia in experimentally inoculated chicks; this neoplasm

prompted the name reticuloendotheliosis but is not commonly seen in the field.

Transmission and Epidemiology:

Horizontal transmission is probably more important than vertical, although both have been documented in chickens and turkeys. Transmission by mosquitoes and other blood-sucking insects is suspected. The virus has been isolated from litter. A high rate of congenital infection has been demonstrated in naturally infected turkeys, but such flocks are probably rare. The virus has been transmitted accidentally through use of contaminated vaccines. Most commonly, however, flocks seroconvert after 10 wk of age without clinical disease or viral shedding to progeny. Experimentally, contact transmission occurs, but the virus is neither highly contagious nor highly stable in the environment. Partial or complete genomic insertion of reticuloendotheliosis virus in the genome of other avian viruses, namely fowlpox and Marek's disease viruses, has been described. However, the significance of such insertion in transmission of reticuloendotheliosis virus is not known. Although semen from tolerantly infected turkeys contains infectious virus, the role of the tom in vertical transmission is not clear.

Pathogenesis: The nondefective strains of reticuloendotheliosis virus produce three distinct syndromes: non-neoplastic runting, acute neoplastic disease, and chronic neoplastic disease resulting in B and T lymphomas. Typically, the runting syndrome is seen 4–10 wk after administration of contaminated vaccines to day-old chicks, which can lead to dramatic economic losses. Chronic neoplastic disease has been induced experimentally in chickens, turkeys, and ducks; one type occurs in chickens after latent periods of >4 mo and appears identical to lymphoid leukosis. As in lymphoid leukosis, these tumors are composed of B cells, are bursal-dependent, and have IgM on their surface. Acute neoplasia, which occurs after a latent period of 6–8 wk, also has been seen in chickens, turkeys, ducks, and quail. This tumor in chickens involves T cells and may be confused with Marek's disease.

Clinical Findings and Lesions: The clinical findings for runting syndrome include weight loss, paleness, occasional paralysis, and abnormal feathering (Nakanuke disease). Death from acute or chronic neoplasia is preceded by depression and occasionally by some of the same clinical changes described for the runting syndrome.

The abnormal feather lesion, in which the barbules are compressed to the shaft over a small part of its length, may be of diagnostic value. Other lesions include bursal and thymic atrophy, enlarged nerves, and anemia. Neoplasms typically involve the liver, spleen, intestine, and heart. The bursa is involved in the chronic B-cell lymphomas of chickens in a manner similar to that of lymphoid leukosis. Nonbursal (T-cell) lymphomas with shorter latent periods and lesions superficially resembling those of Marek's disease also are recognized in chickens. In turkeys, prominent lesions include enlarged livers and nodular lesions on the intestines; the bursa is only rarely tumorous. The tumors, regardless of type or host species, are usually composed of uniform, large, lymphoreticular cells.

Diagnosis: Because lesions induced by reticuloendotheliosis virus are so diverse and resemble so closely those of other tumors, diagnosis at necropsy is difficult. A diagnosis of reticuloendotheliosis requires not only the presence of typical gross and microscopic lesions but also the demonstration of reticuloendotheliosis virus. Because reticuloendotheliosis virus is not yet as ubiquitous as avian leukosis and Marek's disease viruses, the demonstration of infectious virus, viral antigens, and proviral DNA in tumor cells has significant diagnostic value. The nerve lesions are usually less extensive and may contain more plasma cells than in Marek's disease, but in other cases are difficult to differentiate by histology. The runtting syndrome is easily confused with immunosuppressive syndromes caused by other viral agents. The chronic B-cell lymphomas induced experimentally in chickens cannot easily be distinguished from those of lymphoid leukosis except by virus studies, including PCR. Similarly, the T-cell lymphomas of chickens cannot easily be distinguished from Marek's disease except by virus studies. However, both B- and T-cell lymphomas induced by reticuloendotheliosis virus contain a clonally integrated DNA provirus usually associated with the *c-myc* oncogene, which can be demonstrated by appropriate molecular methods. The chronic lymphomas that are seen in turkeys must be differentiated from lymphoproliferative disease of turkeys based on histology, virus isolation, and characterization of the virus-associated reverse transcriptase for activity in the presence of manganese or magnesium ions. Techniques based on immunocytochemistry with monoclonal antibodies to cellular, tumor,

and viral antigens, or molecular hybridization can be used in the differential diagnosis of avian viral lymphomas, including reticuloendotheliosis.

Control: No control measures are currently practiced. An experimental recombinant fowlpox virus vaccine has been developed. Some breeder companies wish to avoid seroconversion of their primary breeder stocks to obviate restrictions on export of progeny to certain countries, but reliable techniques to prevent horizontal transmission have not been developed. Elimination of vertical transmission would presumably be possible by removing potential transmitter hens; rearing progeny under isolated conditions would prevent horizontal infection. Many of these principles have successfully been applied to the control of avian leukosis virus in chickens. Such control procedures could be considered if reticuloendotheliosis virus infection becomes endemic in especially valuable breeding stock, as was the case with reticuloendotheliosis virus infection in the endangered Attwater's prairie chickens.

NEOPLASMS OF UNKNOWN ETIOLOGY

Of the numerous tumors of unknown etiology in poultry, dermal squamous cell carcinoma (avian keratoacanthoma), multicentric histiocytosis, and adenocarcinomas are the most common but appear to be of limited economic importance.

Avian Keratoacanthoma: These neoplasms can occur at relatively high frequencies in some broiler flocks. Carcasses with extensive lesions are condemned at slaughter, while less affected birds undergo trimming. Condemnations of whole carcasses represent a significant economic loss. Typically, the lesions are seen during processing after the skin has been defeathered as crater-like ulcers with raised margins within feather tracts. In live chickens, the ulcers usually contain a mixture of keratin, cell debris, and bacteria. Histologically, lesions appear as proliferative expansion of feather follicle epithelium. An etiologic agent has not yet been identified, and the true neoplastic nature of the lesion has not been confirmed. Transmissibility of this tumor has neither been demonstrated nor excluded.

Multicentric Histiocytosis: This condition of young broiler chickens is characterized by both splenomegaly and

hepatomegaly. Miliary (0.5–5 mm), white to yellow nodules can be seen in the spleen, liver, and kidneys. Microscopically, nodules of spindle-shaped cells diffusely expand periarteriolar lymphoid sheaths. These histiocytic cells contain elongated oval, fusiform, or more bizarrely configured nuclei. No definitive etiologic agent has been identified. A somewhat similar condition with lesions, termed “histiocytic sarcomatosis,” has been described in meat-type chickens experimentally

infected with subgroup J avian leukosis virus.

Adenocarcinomas: Adenocarcinomas of the ovary or oviduct are relatively common incidental tumors in mature chickens. These neoplasms often are characterized by multiple military implant tumors on the mesentery and other visceral surfaces, frequently accompanied by ascites. These tumors are not known to be virus-induced or to be transmissible.

NEWCASTLE DISEASE AND OTHER PARAMYXOVIRUS INFECTIONS

NEWCASTLE DISEASE

(Avian pneumoencephalitis, Exotic or velogenic Newcastle disease)

Newcastle disease is an infection of domestic poultry and other bird species with virulent Newcastle disease virus (NDV). It is a worldwide problem that presents primarily as an acute respiratory disease, but depression, nervous manifestations, or diarrhea may be the predominant clinical form. Severity depends on the virulence of the infecting virus and host susceptibility. Occurrence of the disease is reportable and may result in trade restrictions.

Etiology and Pathogenesis: NDV, synonymous with avian paramyxovirus serotype 1 (PMV-1), is an RNA virus and the most important of the 11 known PMV serotypes as a pathogen for poultry. The original classification of NDV isolates into one of three virulence groups by chicken embryo and chicken inoculation as virulent (velogenic), moderately virulent (mesogenic), or of low virulence (lentogenic) has been abbreviated for regulatory purposes. Velogens and mesogens are now classified as virulent NDV (vNDV), the cause of Newcastle disease and reportable infection, whereas infections with lentogens, the low virulence NDV (lNDV) widely used as live vaccines, are not reportable. Clinical manifestations vary from high morbidity and mortality to asymptomatic infections. Severity of infection depends on virus virulence and age, immune status, and susceptibility of the host species. Chickens are the most and waterfowl the least susceptible of domestic poultry; however,

some differences may be seen if the NDV strain is adapted to a particular species.

Epidemiology and Transmission: Virulent NDV strains are endemic in poultry in most of Asia, Africa, and some countries of North and South America. Other countries, including the USA and Canada, are free of those strains in poultry and maintain that status with import restrictions and eradication by destroying infected poultry. Cormorants, pigeons, and imported psittacine species are more commonly infected with vNDV and have also been sources of vNDV infections of poultry. NDV strains of low virulence are prevalent in poultry and wild birds, especially waterfowl. Infection of domestic poultry with lNDV contributes to lower productivity.

Infected birds shed virus in exhaled air, respiratory discharges, and feces. Virus is shed during incubation, during the clinical stage, and for a varying but limited period during convalescence. Virus may also be present in eggs laid during clinical disease and in all parts of the carcass during acute vNDV infections. Chickens are readily infected by aerosols and by ingesting contaminated water or food. Infected chickens and other domestic and wild birds may be sources of NDV. Movement of infected birds and transfer of virus, especially in infective feces, by the movement of people and contaminated equipment or litter are the main methods of virus spread between poultry flocks.

Clinical Findings: Onset is rapid, and signs appear throughout the flock within 2–12 days (average 5) after aerosol exposure. Spread is

slower if the fecal-oral route is the primary means of transmission, particularly for caged birds. Young birds are the most susceptible. Observed signs depend on whether the infecting virus has a predilection for respiratory, digestive, or nervous systems. Respiratory signs of gasping, coughing, sneezing, and rales predominate in infections with lNDV. Nervous signs of tremors, paralyzed wings and legs, twisted necks, circling, clonic spasms, and complete paralysis may accompany, but usually follow, the respiratory signs in neurotropic velogenic disease. Nervous signs with diarrhea are typical in pigeons, and nervous signs are frequently seen in cormorants and exotic bird species. Respiratory signs with depression, watery greenish diarrhea, and swelling of the tissues of the head and neck are typical of the most virulent form of the disease, viscerotropic velogenic Newcastle disease, although nervous signs are often seen, especially in vaccinated poultry. Varying degrees of depression and inappetence are seen. Partial or complete cessation of egg production may occur. Eggs may be abnormal in color, shape, or surface and have watery albumen. Mortality is variable but can be as high as 100% with vNDV infections. Well-vaccinated birds may not show any signs of being infected except for a decrease in egg production, but these birds will shed virus in saliva and feces. Poorly vaccinated birds may develop torticollis, ataxia, or body and head tremors 10–14 days after infection and may recover with supportive care.

Lesions: Remarkable gross lesions are usually seen only with viscerotropic velogenic Newcastle disease. Petechiae may be seen on the serous membranes; hemorrhages of the proventricular mucosa and intestinal serosa are accompanied by multifocal, necrotic hemorrhagic areas on the mucosal surface of the intestine, especially at lymphoid foci such as cecal tonsils. Splenic necrosis and hemorrhage and edema around the thymus may also be seen. In contrast, lesions in birds infected with lNDV strains may be limited to congestion and mucoid exudates seen in the respiratory tract with opacity and thickening of the air sacs. Secondary bacterial infections increase the severity of respiratory lesions.

Diagnosis: NDV can be isolated from oropharyngeal or cloacal swabs or tissues from infected birds by inoculation of the allantoic cavity of 9- to 11-day-old SPF embryonated chicken eggs. Infection is confirmed by recovery of a hemagglutinating

virus that is inhibited with NDV antiserum or by detection of NDV RNA by reverse transcriptase PCR. A rise in NDV antibody titer by hemagglutination-inhibition or ELISA of paired serum samples indicates NDV infection. To confirm diagnosis, identification of an isolate such as vNDV is established by the rapidity of killing day-old SPF chicks inoculated by the intracerebral route, the intracerebral pathogenicity index, or by the presence of a specified amino acid motif at the cleavage site of the fusion protein (F) precursor (FO). Reference laboratories use nucleotide sequence analysis to detect genetic differences for comparison of isolates from different outbreaks and to identify the source of those infections. The acute form of ND should be differentiated from other diseases known to cause high mortality, such as highly pathogenic avian influenza (see p 2902).

Prevention: Vaccines are available for chickens, turkeys, and pigeons and are used to induce an antibody response, so vaccinated birds must be exposed to a larger dose of vNDV to be infected. Unfortunately, ND vaccines do not provide sterile immunity, and in many areas of the world vaccines are used to prevent losses from sickness and death. Live lentogenic vaccines, chiefly B1 and LaSota strains, are widely used and typically administered to poultry by mass application in drinking water or by spray. Mucosal immunity induced in birds vaccinated by live vaccines applied by these routes decreases the amount of vNDV the vaccinated birds will shed if infected with vNDV, compared with the immune response induced by an inactivated vaccine. Mass vaccination methods are less labor intensive but if not applied properly may lead to <85% of the flock being immunized, which is needed for herd immunity. Alternatively, individual administration of live vaccines is via the nares or conjunctival sac. Healthy chicks are vaccinated as early as day 1–4 of life. However, delaying vaccination until the second or third week avoids maternal antibody interference with an active immune response. *Mycoplasma*, some other bacteria, and other viruses affecting the respiratory tract, if present, may act synergistically with some vaccines to aggravate the vaccine reaction after spray administration.

Oil-adjuvanted inactivated vaccines are also used after live vaccine in breeders and layers and may be used alone in situations where use of live virus may be contraindicated (eg, in pigeons). In countries where vNDV is endemic, a combination of live

virus and inactivated vaccine can be used; or alternatively, if permitted by law, a live mesogenic strain vaccine may be used in older birds. The frequency of revaccination to protect chickens throughout life largely depends on the risk of exposure and virulence of the field virus challenge. Administering inactivated vaccines is more labor intensive, because each bird has to be handled individually. Accidental inoculation of human tissues with oil-based vaccines requires prompt medical treatment.

Fowlpox or turkey herpesvirus–vectored NDV vaccines are commercially available for chickens and have the advantage of being able to be administered in ovo at the hatchery. These vaccines must be reconstituted as directed by the manufacturer and, because they take 3–4 wk to produce a protective level of immunity, biosecurity is even more important. A commercial kit to detect levels of antibodies induced by these vaccines is not yet available.

Zoonotic Risk: All NDV strains can produce a transitory conjunctivitis in people, but the condition has been limited primarily to laboratory workers and vaccination teams exposed to large quantities of virus. Before poultry vaccination was widely practiced, conjunctivitis from NDV infection occurred in crews eviscerating poultry in processing plants. The disease has not been reported in people who rear poultry or consume poultry products.

OTHER AVIAN PARAMYXOVIRUS INFECTIONS

Avian paramyxovirus infections have been reported in chickens and turkeys in association with respiratory disease or decreases in egg production.

Etiology and Epidemiology: There are 12 recognized serotypes of avian paramyxoviruses (PMV-1 to PMV-12). Newcastle disease virus (PMV-1, *see* p 2856) is the most important pathogen of this group for poultry, but PMV-2, -3, -6, and -7 are occasionally associated with disease in chickens and turkeys. The most recent serotypes (PMV-10, -11, and -12) were isolated from Rockhopper penguin (*Eudyptes chrysocome*) in the Falkland Islands, Common Snipe (*Gallinago gallinago*) in France, and Eurasian Widgeon (*Anas penelope*) in Italy, respectively, and were the first new serotypes in >30 yr.

PMV-2 has been isolated from wild birds, mainly passerines, and caged psittacine

species. Primary infections in poultry are believed to be the result of contact with wild birds. The method of transmission to chickens or turkeys is unclear. PMV-3 has been isolated from imported exotic and other bird species held in captivity. Psittacines appear to be the primary host, although PMV-3 will spread among passerines in captivity. There are no reports of isolation of PMV-3 from wild birds. The method of transmission among turkeys is unclear, and spread within a flock is usually slow.

Clinical Findings: Infections by PMV-2, -3, -6, and -7 in turkeys have produced mild to severe respiratory disease, drops in egg production, reduced hatchability and infertility of eggs, and increased numbers of white-shelled eggs. Infection with PMV-2 has produced mild respiratory disease in chickens, but PMV-2 infection is usually most severe in turkeys, especially breeders. Infection is more severe when accompanied by secondary pathogens.

Diagnosis: Most diagnoses are made by clinical signs and confirmed by serology. PMV-2, -3, -6, and -7 can be isolated from oropharyngeal or cloacal swabs, or tissue samples from infected birds by inoculating the allantoic cavity of 8- to 10-day-old embryonating chicken eggs. Confirmation of the virus as PMV can be done by hemagglutination inhibition tests with specific antiserum to individual serotypes. However, PMV-1 (Newcastle disease virus) and PMV-3 may cross-react in hemagglutination inhibition tests (and in other serologic tests such as ELISA), which causes interpretation problems in vaccinated birds. Birds vaccinated against Newcastle disease show a rise in hemagglutination inhibition titers to both viruses if subsequently infected with PMV-3.

Prevention and Control: No vaccines are available for PMV-2, -6, and -7. Inactivated oil-emulsion vaccines against PMV-3 have been used in turkey breeder flocks. These are injected twice, 4 wk apart, before the birds begin to lay (usually when 20–24 wk old). The risk of introducing PMV-2 and other paramyxoviruses from wild birds may be minimized by bird-proofing poultry houses and using good hygiene and biosecurity practices. Treatment of secondary bacterial infections with antibiotics has had some success. PMV-3 appears to spread slowly.

Zoonotic Risk: No human infections have been reported for PMV-2 to PMV-12 viruses.

OMPHALITIS

(Navel ill, "Mushy chick" disease, Yolk sac infection)

Omphalitis is a condition characterized by infected yolk sacs, often accompanied by unhealed navels in young fowl. It is infectious but noncontagious and is associated with poor regulation of incubation temperature or humidity and marked contamination of the hatching eggs or incubator. If young poultry are placed in contaminated transportation boxes before their navels are completely closed, bacteria can migrate up the patent yolk stalk and infect the yolk sac.

The navel may be inflamed and fail to close, producing a wet spot on the abdomen; a scab may be present. Opportunistic bacteria (coliforms, staphylococci, *Pseudomonas* spp, and *Proteus* spp) are often involved, and mixed infections are common. Proteolytic bacteria are prevalent in outbreaks. The yolk sac is not absorbed and often is highly congested or may contain solidified pieces of yolk material; peritonitis may be extensive. Edema of the sternal subcutis may be seen. Affected chicks or poults usually appear normal until a few hours before death. They have little interest in food and water and are often found severely dehydrated. Depression, drooping of the head, and huddling near the heat source usually are the only signs. Mortality often begins at hatching and continues to 10–14 days of age, with losses of as much as 15% in chickens and 50% in turkeys. Chilling or overheating during shipment may increase losses. Persistent,

unabsorbed, infected yolks often produce chicks or poults with reduced weight gain.

There is no specific treatment; antibiotic use is based on the prevalent bacterial type involved. Even then, treatment may not result in satisfactory outcomes, because severely affected chicks and poults often die, and unaffected birds are unlikely to be aided by antibiotic treatment. The disease is prevented by careful control of temperature, humidity, and sanitation in the incubator. Only clean, uncracked eggs should be set. If it is necessary to set dirty eggs, they should be segregated from clean eggs. Sanitizing detergents must be used according to directions if eggs are washed. Time, temperature, and frequent changes of water are as critical as the concentration of sanitizer in both wash and rinse water. The rinse should be warmer than the wash water (which should be warmer than the internal temperature of the egg) but should not be >60°C.

The incubator should be cleaned and disinfected thoroughly between hatches. If fumigation is to be done with formaldehyde, vents should be closed. Thirty mL of 40% formaldehyde/0.6 m³, or paraformaldehyde (in the strength recommended by the manufacturer), should be allowed to evaporate in the closed incubator or hatchery. The machines are readily contaminated after fumigation unless the exterior of the machines and the rooms in which they are located are also cleaned and disinfected.

POISONINGS

See also TOXICOLOGY, p 2948 et seq.

When toxicosis in a poultry flock is suspected based on mortality, on decreased production/growth, or on other clinical signs such as paralysis, the flock owner or veterinarian should maintain and allow access to historical records. These records include use of disinfectants and rodenticides and insecticides on the premises, medications administered in feed and water, and nutritional additives to the feed. Samples to

be collected for potential analysis in cases of suspected toxicosis include dead or recently euthanized birds that showed clinical signs, 2 lb (1 kg) of the feed available when the birds were showing clinical signs, and 500 mL of drinking water. For the safety of workers as well as poultry, the grower should have access to material safety data sheets for each chemical used on the premises. Carcasses should be refrigerated as soon as possible for examination by the

veterinarian or laboratory diagnostician. Consultation with a toxicologist or laboratory diagnostician before collecting samples is highly recommended.

Aflatoxin: Aflatoxicosis is one of the most common intoxications in modern poultry production systems. Certain species of *Aspergillus* and *Penicillium* can produce aflatoxins in feedstuffs. The production of aflatoxins can occur either in the field where the crops are grown or during storage. Acute aflatoxicosis is characterized by inappetence, ataxia, convulsions, opisthotonos, depression, and death. A gross lesion often seen with acute aflatoxicosis is an enlarged yellow liver. All poultry are susceptible to aflatoxicosis; however, ducks and turkeys are particularly sensitive.

Ammonia (aerosolized): Ammonia gas is produced by the metabolism of uric acid by bacteria that can thrive in wet poultry litter. High ammonia levels often occur during the winter when ventilation is minimized to conserve heat and thus high litter moisture is common. Increased ammonia levels of 25–30 ppm can damage the mucociliary apparatus of the upper respiratory tract, and higher levels (50–75 ppm) can cause decreased feed intake as well as caustic burns to the cornea, which can result in blindness. These birds will often fail to find adequate food and water, resulting in death.

Anticoagulant Rodenticides: Rodenticides can be safely applied to poultry houses so that rodent baits are sequestered from the flock; however, careless applica-

tion can result in rodent bait consumption by poultry with usually acute toxic effects. First-generation anticoagulant rodenticides, including warfarin, chlorphacinone, diphacinone, and coumatetralyl, require continual ingestion by rodents to induce toxic effects. Second-generation or single-feed anticoagulants, including brodifacoum, bromadiolone, difenacoum, and difethialone, can be acutely fatal to rodents. Clinical signs in poultry are related to the anticoagulant effects and usually observed as sudden death with gross hemorrhagic lesions in one or more body sites, particularly lung, intestine, and peritoneal cavity. These lesions can be confused with flight injury (gamebirds) and trauma from wild animals and dogs. Definitive diagnosis of anticoagulant toxicosis should be based on gross lesions, history of anticoagulant application, and anticoagulant screen on liver of dead birds (available at several USA veterinary diagnostic laboratories).

Botulism: *Clostridium botulinum* bacteria produce several exotoxins that are among the most potent toxins known. In ducks and geese, botulism outbreaks commonly occur in the summer months in the vicinity of poorly aerated ponds and lakes. The waterfowl ingest the toxin by eating dead invertebrates from the margins of these lakes or eating maggots on the carcasses of ducks that have already succumbed to the intoxication. In pheasant and broiler flocks, where the timely removal of dead birds has not been practiced, carcasses can also become a source of toxin. The classic clinical sign of botulism intoxication in poultry is paralysis of the muscles of the neck or “limberneck.” The toxin also causes paralysis affecting the legs, wings, and eyelids. Diagnosis of botulism is often based on exclusion of other possible causes, although intestinal contents and blood can be collected for botulism toxin analysis (mouse inoculation assay), which is available at several USA diagnostic laboratories.

Calcium: Excessive calcium intake in broiler chicks results in urolithiasis and visceral gout (hyperuricemia) with urate deposits on the abdominal viscera and in the joints. Tetanic convulsions can also be seen in chicks consuming excess calcium. Calcium levels >2% will induce these lesions in broilers. Feeding calcium in excess of 3% before the onset of egg production will induce the same lesions in egg-type or meat-type pullets.

Pullets exposed to high levels of aerosolized ammonia^a wet litter developed blindness as a result of corneal ulcers. Courtesy of Dr. Robert Porter.

Carbon Monoxide: This poisoning commonly arises from exhaust fumes when chicks are being transported by truck or from improper ventilation in hatcheries. Mortality may be high unless fresh air is provided immediately. At necropsy, the beak and face are cyanotic, and a characteristic bright pink color is noted throughout the viscera, particularly the lungs. ■ Diagnosis can be confirmed by a spectroscopic analysis of the blood.

Coffee Weed Seed: *Senna obtusifolia* seeds are frequently found in corn and soybeans. When present at $\geq 2\%$, they reduce feed intake and lower body weight, increase feed conversion in broilers, and significantly depress egg production in laying birds. Necropsy lesions are absent.

Copper: Copper sulfate has been used as a water additive for treatment of crop mycosis (*Candida* overgrowth) or nonspecific digestive tract disorders in poultry. Copper sulfate in a single dose of > 1 g is fatal. The signs are watery diarrhea and listlessness. A catarrhal gastroenteritis and burns or erosions in the lining of the gizzard, accompanied by a greenish, seromucous exudate throughout the intestinal tract, are found at necropsy.

Crotalaria: Seeds of many species are toxic to chickens. Concentrations $> 0.05\%$ in the feed produce signs of toxicosis. At 0.2% , weight gain is reduced markedly; 0.3% causes death in 18 days. Lesions consist of ascites, swelling or cirrhosis of the liver, and hemorrhages. Resistance to the toxin increases with age.

Diazinon: ■ Diazinon is an organic phosphate and cholinesterase inhibitor commonly used to control a variety of insects around poultry houses. It should not be used inside poultry houses. Chickens will consume the diazinon crystals, which results in lacrimation, diarrhea, dyspnea, and death. Necropsy lesions include lung edema, fatty livers, and severe enteritis. The diazinon crystals might be seen in the crop and gizzard contents. ■ Diagnosis can be confirmed by testing brain for cholinesterase activity.

Gossypol: Cottonseed meal contains appreciable amounts of gossypol, which produces severe cardiac edema that results in dyspnea, weakness, and anorexia. When fed to laying hens, gossypol also causes egg-yolk discoloration.

Lead: Lead poisoning usually is caused by paint or orchard-spray material. Metallic lead in amounts of 7.2 mg/kg body wt is lethal. Signs are depression, inappetence, emaciation, thirst, and weakness. Greenish droppings are commonly seen within 36 hr. As poisoning progresses, the wings may be extended downward. Young birds may die within 36 hr after ingestion. Acute lead poisoning may be diagnosed from the history and necropsy findings of a greenish brown gizzard mucosa, enteritis, and degeneration of the liver and kidney. Chronic poisoning results in emaciation and in atrophy of the liver and heart. The pericardium is distended with fluid, the gallbladder is thickened and enlarged, and urate deposits are usually found in the kidneys. Ingestion of lead shot often occurs in wild waterfowl on heavily gunned feeding grounds. Retention of only a few lead pellets in the gizzard can kill a duck.

Mercury: Poisoning occurs from mercurial disinfectants and fungicides, including mercurous chloride (calomel) and bichloride of mercury (corrosive sublimate). Clinical findings are progressive weakness and incoordination. ■ Diarrhea may occur, depending on the amount ingested. The caustic action of the chemical may produce gray areas in the mouth and esophagus, which usually ulcerate if the bird lives > 24 hr. Catarrhal inflammation of the proventriculus and intestines may occur; if a large amount of mercury is ingested, extensive hemorrhage may occur in these organs. The kidneys are pale and studded with small, white foci. The liver shows fatty degeneration.

Nicarbazin: This chemical coccidiostat is used in broilers. It should not be fed to layers, because it can cause discoloration and reduced hatchability of eggs (although the effect is reversible once the nicarbazin is withdrawn). It also may result in reduced heat tolerance in birds exposed to high temperature and humidity.

Nitrofurazone: This has been used to treat several bacterial diseases in poultry, but it is no longer approved for use in many countries, including the USA. When fed at 0.022% , it causes hyperexcitability manifest by rapid movements, loud squawking, and frequent falling forward. In turkeys, which are more sensitive to nitrofurazone than are chickens, it produces cardiac dilatation, ascites, and when fed at 0.033% , death.

3-Nitro-4-hydroxyphenylarsonic Acid: When this compound, widely used in feed to improve weight gain and feed efficiency, is

improperly mixed or fed at a level 2–3 times higher than normal, it induces a high-pitched chirp and a “duck-walking” stance. Ataxia, neck extension, and paralysis can occur in chickens and turkeys that consume excessive amounts. Clinical signs are usually reversible in a few minutes. Chronic exposure may produce intrahepatic cholangitis.

Polychlorinated Biphenyls (PCBs):

Residues have been reported in the fatty tissue of chickens and turkeys in excess of the 5 ppm permitted in edible tissue, and in egg products in excess of the permitted 0.5 ppm. PCBs depress egg production and hatchability, and levels of 50 ppm result in cirrhosis of the liver and ascites in broilers and a drop in egg production and hatchability in hens. (See also **PERSISTENT HALOGENATED AROMATIC POISONING**, p 3056.)

Polyether Ionophores: Polyether ionophores facilitate transport of divalent cations across cell membranes to interfere with osmoregulation, resulting in cell rupture. Toxicosis caused by ionophores is relatively common in poultry, because these compounds are commonly administered for the prevention and treatment of coccidiosis and are subject to overdosing and mixing errors. Additionally, these ionophores can interact with certain medications, such as sulfonamides, to cause toxicosis signs when the ionophore concentration in the feed is normal. Examples of ionophores used in poultry are described below.

Lasalocid: Lasalocid is an anticoccidial compound that has been used in hot summer months, because it increases water consumption. When used at other times of the year, the level of salt in the ration is reduced to prevent excessive water elimination and wet litter problems. If the salt level is reduced too much, it will result in stunting, increased lameness, and a characteristic clinical picture in broilers manifested by the bird walking on its toes. This clinical syndrome has been called lasalocid toxicity when, in reality, it is due to low levels of salt in the feed.

Monensin: This ionophore coccidiostat is widely used in the broiler industry. At levels >120 ppm it reduces feed intake and weight gain; in layers, egg production is reduced. Signs of toxicity include a characteristic paralysis in which the legs are extended backward. If naive turkeys are switched to a feed that contains monensin, they become paralyzed with the legs extended backward and mortality occurs; no lesions are seen at necropsy.

Narasin: This ionophore is often administered in combination with the chemical nicarbazone to prevent coccidiosis in broilers but can be particularly toxic in turkeys (often noted on product label), resulting in flaccid paralysis of the wings and legs. Toxic effects have also been described in broilers simultaneously treated with tiamulin or sulfonamides.

Salinomycin: Salinomycin is commonly used as an anticoccidial compound in the broiler industry. It is safe when used at 60 g/ton of feed. Toxicities occur when broiler feed containing salinomycin is accidentally fed to naive breeder hens. Clinical signs in these hen flocks include paralysis with the legs extended backward and decreased feed consumption, egg production, and hatchability. Levels of salinomycin >10 g/ton in breeder-hen feed are sufficient to produce these clinical signs. Necropsy lesions are absent in birds with this clinical picture.

Polytetrafluoroethylene (PTFE):

PTFE is a synthetic fluoropolymer resin highly resistant to heat and chemically stable with low reactivity. PTFE has been used as nonstick coating for frying pans (Teflon®) and has been used to coat heat lamps and heater filaments that might be used in poultry houses. Although generally heat stable, PTFE heated above 280°C (536°F) can produce aerosolized hydrogen fluoride, carbon fluoride, carbon monoxide, and low-molecular-weight fluoropolymers. PTFE pyrolysis products can cause direct caustic damage to the lung, resulting in marked pulmonary edema and hemorrhage. Birds are often found dead with no premonitory signs. Diagnosis is based on gross lesions, history of using new heating lamps or filaments coated with PTFE, and excluding other possible causes of pulmonary hemorrhage.

Propane: Propane is commonly used in poultry facilities as a fuel source to provide heat for young poultry. Chicks are often surrounded by a cardboard brooder ring to provide a safe, warm environment during the first week of life. If a defective heater leaks propane into the brooder ring, the propane gas will displace the lighter air, resulting in asphyxiation of the chicks. On necropsy, these chicks have congested, edematous lungs that sink when placed in formalin.

Quaternary Ammonia: Quaternary-ammonia-based compounds are widely used as disinfectants. (See also **ANTISEPTICS AND**

DISINFECTANTS, p 2738.) Turkeys are very sensitive; levels of 150 ppm result in substantial mortality. Clinical signs include reduced water intake, nasal and ocular discharge, facial swelling, and gasping. Necropsy lesions include caseous ulcers at the base of the tongue and commissures of the mouth.

Selenium: Ingestion of feeds containing >5 ppm of selenium decreases the hatchability of eggs due to deformities of the embryos, which are unable to emerge from the shell because of beak anomalies. Eyes may be unilaterally hypoplastic or aplastic, and feet and wings may be deformed or underdeveloped. Selenium at 10 ppm, as in seleniferous grains in the laying ration, usually reduces hatchability to zero. Young laying hens entering egg production are more susceptible than older hens.

Mature birds seem to tolerate more selenium in their feed than do pigs, cattle, or horses and do not exhibit signs of poisoning other than poor hatchability of their eggs. Starting rations containing 8 ppm selenium have reduced the growth rate of chicks, but 4 ppm had no noticeable effect. Rations containing as little as 2.5 ppm have resulted in meat and eggs with concentrations of selenium in excess of the suggested tolerance limit in foods. Sodium arsenite and some of the organic arsenicals, when administered to laying hens with selenium, have increased hatchability.

Sodium (salt): The addition of 0.5% salt (NaCl) to the ration of chickens and turkeys is recommended, but amounts >2% are usually considered dangerous. Rations for chicks have contained as much as 8% without injurious effect, but in poults, rations containing 4% were harmful and levels of 6%–8% have resulted in mortality. The addition of 2% NaCl to the feed, or 4,000 ppm in the water, depresses growth in young ducks and lowers the fertility and hatchability of the eggs in breeding stock.

Salt levels high enough to produce poisoning may be reached when salty protein concentrates (eg, fish meal) are added to rations already fortified with salt or when the salt is poorly incorporated in the feed. Sporadic poisoning also has been reported from accidental ingestion of rock salt or salt provided for other livestock. Necropsy findings are not diagnostic; enteritis and ascites are common. Watery droppings and wet litter often are suggestive of a high salt intake. Edema of the

testicle is pathognomonic of salt toxicity in young birds.

Sulfonamides: Sulfonamides are widely used for treatment of several bacterial and protozoal infections in poultry and are usually administered in drinking water. Sulfaquinoxaline, when fed at 0.25%, results in severe pancytopenia. Hemorrhages are common on the legs, breast muscle, and in virtually all abdominal organs. The bone marrow is pale, and the blood is slow to clot. Toxicity is frequently seen in hot weather when sulfaquinoxaline is provided in drinking water. Water consumption increases rapidly as the temperature increases, which leads to increased drug intake. This toxicity usually is responsive to vitamin K therapy.

Sulfur: Elemental sulfur is often used in broiler houses in an attempt to improve growth rate and feed conversion and to minimize bacterial disease. The compound is applied to the floor after the litter has been removed. Elemental sulfur is also used in dust baths for treatment of ectoparasites in adult layers. If the amount of new litter placed in the house is inadequate, young chicks will come in contact with the sulfur, resulting in conjunctivitis and cutaneous burns, especially under the wings and on the legs. Clinically, the birds appear cold and tend to huddle; in many instances, death will occur due to the birds piling up, causing overheating and suffocation. When sulfur comes into contact with moisture, sulfuric acid is produced, which results in the burns.

Thiram: Thiram is used to treat seed corn. It is toxic to chicks at 40 ppm and to goslings at 150 ppm; it causes leg deformities and weight loss. At 10 ppm, it causes soft-shelled eggs, and at 40 ppm, egg production and hatchability are reduced. Turkey poults tolerate up to 200 ppm.

Toxic Fat: A crystalline halogen has been identified as the “toxic fat” factor in some feeds. In young pullets, it reduces growth, retards sexual development, and increases mortality. Hatchability is decreased. Turkeys and ducks are less susceptible than chickens. Signs of intoxication include ruffled feathers, droopiness, and dyspnea. Lesions include ascites and hydropericardium, liver necrosis, subepicardial hemorrhage, and bile duct hyperplasia. Although the amount of toxin varies in feeds from different sources, 0.25%–0.5% fed for 35–150 days produces typical lesions.

RIEMERELLA ANATIPESTIFER INFECTION

(New duck disease, Infectious serositis, *Pasteurella anatipestifer* infection)

Infection with *Riemerella anatipestifer* is a contagious, widely distributed bacterial disease that primarily affects young ducks and less frequently turkeys and geese. Other waterfowl, chickens, and pheasants occasionally may be affected.

Etiology and Transmission: *R. anatipestifer* is gram-negative, nonsporulating, catalase and oxidase positive, and non-motile. It grows microaerophilically in enriched media. *R. anatipestifer* possesses few characteristic phenotypic properties, so isolation and identification procedures should be polyphasic. A definitive diagnosis should include genotypic identification (PCR amplification of a partial region of the *rpoB* or the 16S rRNA gene with subsequent sequencing is recommended). Just like *Pasteurella multocida*, *R. anatipestifer* includes a number (>20) of immunotypes (or serotypes). This complicates efforts at widespread prevention using bacterins, because no cross-protection occurs between serotypes. However, currently, much effort is on the search for cross-protective vaccine candidates using an immunoproteomics approach.

The epidemiology and pathogenesis are poorly understood. Ducks are believed to be infected from the environment by the respiratory route or when *R. anatipestifer* is introduced into lesions of the webbed foot. Turkeys may be infected by injuries or by the respiratory route when another pathogen disrupts the respiratory epithelium. Once the infection is established on a farm, it frequently becomes endemic.

Clinical Findings and Lesions: Signs usually develop after an incubation period of 2–5 days. Affected ducks, usually 1–7 wk old, often have ocular and nasal discharges, mild coughing and sneezing, tremors of the head and neck, and incoordination. In typical cases, affected ducklings lie on their backs, paddling their legs. Stunting may occur. Necrotic dermatitis on the lower back or around the vent may also be seen. Fibrinous exudate in the pericardial cavity and over the surface of the liver is the most characteristic lesion. Fibrinous airsacculitis is common, and infection of the CNS can result in fibrinous meningitis. The spleen and liver may be swollen. Pneumonia may

be seen. Mortality is usually 2%–50%. A high proportion of affected birds develop mucopurulent or caseous salpingitis. Affected breeding stock should be slaughtered, because many become blind layers.

Affected turkeys, usually 5–15 wk old, often exhibit dyspnea, droopiness, hunched back, lameness, and a twisted neck. Fibrinous pericarditis and epicarditis are the most pronounced lesions. There may also be fibrinous perihepatitis, airsacculitis, and purulent synovitis. Osteomyelitis, meningitis, and focal pneumonia are seen occasionally. Mortality is 5%–60%, and condemnations are 3%–13%.

Diagnosis: Diagnosis is based on typical CNS signs (if present), lesions, and isolation and identification of the causative organism (using traditional biochemical characterization). Other diseases, eg, colibacillosis (see p 2814), salmonellosis (see p 195), and chlamydiosis (see p 2808), may produce similar lesions. Chocolate agar medium is recommended for isolation, although blood agar is also used, with incubation at 37°C in a candle jar or under 5% carbon dioxide. Several PCR-based diagnostic tests have been described, including assays for the *ompA* gene, 16S rRNA, *rpoB* gene, and an ERIC fragment. The published PCR tests are all able to detect *R. anatipestifer*, but a high rate of false-positive reactions may occur. Consequently, PCR amplification of a partial region of the *rpoB* or the 16S rRNA gene with subsequent sequencing can be recommended to confirm identification. Recently, matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) has been used successfully for identification. The isolate should be serotyped (only a few laboratories are capable), because the information may be needed for vaccine selection and epidemiologic studies. Plate agglutination is rapid and convenient for this purpose. However, unless titrations are carried out, only absorbed sera should be used because of the existence of multiple antigenic factors within a single strain. Biochemical characteristics can be used to differentiate this organism from other bacteria that cause important diseases of ducks and turkeys, particularly *Escherichia coli*, *P. multocida*,

Salmonella enterica, *Coenonia anatine*, *Avibacterium gallinarum*, and *Bordetella avium*. Impression smears help to determine whether chlamydia is involved.

Prevention and Control: Careful management practices are important for prevention of infection. A high level of biosecurity is essential. Cleaning and disinfection between flocks and separation of flocks on multiple-age farms are other factors of major importance. Rigid sanitation and depopulation are necessary for elimination of the disease on endemically infected farms.

A bacterin and, more recently, a live vaccine, which include the three most

common immunotypes of *R anatipestifer*, are available for use in ducks. An autogenous oil-emulsion bacterin can be used in turkeys. Breeder ducks can be vaccinated with a bacterin or live vaccine to provide protection to the ducklings that may last for up to 2–3 weeks of age. A combination of penicillin and streptomycin, or sulfaquinoxaline can be used for initial treatment, but an antibiotic sensitivity test should be performed, because multiresistant strains may develop. Enrofloxacin has also proved highly effective in preventing mortality in ducklings when administered in the drinking water. However, current legislation in many countries does not allow the use of quinolones in production animals.

SALMONELLOSES

Salmonella infections are classified as nonmotile serotypes (*S Pullorum*, *S Gallinarum*) and the many motile paratyphoid *Salmonella*. These *Salmonella* infections have a worldwide distribution. As a result of the institution of a testing and control program in the USA through the USDA-administered National Poultry Improvement Plan, the incidence of *S Pullorum* or *S Gallinarum* has decreased dramatically. Historically, *S Arizonae* was placed in its own category, but it is now included with the paratyphoid *Salmonella*. *S Arizonae* is an egg-transmitted disease primarily of young turkeys. In addition to the above nonmotile salmonellae, *Salmonella* paratyphoid infections in poultry are relatively common and have public health significance because of contaminated poultry product consumption.

S Pullorum and *S Gallinarum* are highly host-adapted to chickens and turkeys. There are >2,500 nonhost-adapted species (paratyphoid) that may be transmitted to almost all animals.

PULLORUM DISEASE

Etiology and Transmission: Infections with *Salmonella Pullorum* usually cause very high mortality (potentially approaching 100%) in young chickens and turkeys within the first 2–3 wk of age. In adult chickens, mortality may be high but frequently there are no clinical signs. Pullorum disease was

once common but has been eradicated from most commercial chicken stock in the USA, although it may be seen in other avian species (eg, guinea fowl, quail, pheasants, sparrows, parrots, canaries, and bullfinches) and in small backyard or hobby flocks. Infection in mammals is rare, although experimental or natural infections have been reported (chimpanzees, rabbits, guinea pigs, chinchillas, pigs, kittens, foxes, dogs, swine, mink, cows, and wild rats).

Transmission can be vertical (transovarian) but also occurs via direct or indirect contact with infected birds (respiratory or fecal) or contaminated feed, water, or litter. Infection transmitted via egg or hatchery contamination usually results in death during the first few days of life up to 2–3 wk of age. Transmission between farms is due to poor biosecurity.

Clinical Findings and Lesions: The disease may be seen in all age groups, but birds <4 wk old are most commonly affected. Birds may die in the hatchery shortly after hatching. Affected birds huddle near a heat source, are anorectic, appear weak, and have whitish fecal pasting around the vent (diarrhea). Survivors are small in size and frequently become asymptomatic carriers with localized infection of the ovary. Some of the eggs laid by such hens hatch and produce infected progeny.

There may be no lesions due to an acute septicemia and death. Lesions in young birds usually include unabsorbed yolk sacs

and classic gray nodules in the liver, spleen, lungs, heart, gizzard, and intestine. Firm, cheesy material in the ceca (cecal cores) and raised plaques in the mucosa of the lower intestine are sometimes seen. Occasionally, synovitis is prominent. Adult carriers usually have no gross lesions but may have nodular pericarditis; fibrinous peritonitis; or hemorrhagic, atrophic, regressing ovarian follicles with caseous contents. In mature chickens, chronic infections produce lesions indistinguishable from those of fowl typhoid (*see below*).

Diagnosis: Lesions may be highly suggestive, but diagnosis should be confirmed by isolation, identification, and serotyping of *S Pullorum*. Infections in mature birds can be identified by serologic tests, followed by necropsy evaluation complemented by microbiologic culture and typing for confirmation. Official testing recommendations for flocks in the USA are outlined in the National Poultry Improvement Plan.

Treatment and Control: Treatment of infected flocks to alleviate the perpetuation of the carrier state is not recommended. Control is based on routine serologic testing of breeding stock to assure freedom from infection. In addition, management and biosecurity measures should be taken to reduce the introduction of *S Pullorum* from feed, water, wild birds, rodents, insects, or people. Birds should be purchased from sources free of *S Pullorum*.

FOWL TYPHOID

Etiology and Epidemiology: The causal agent is *Salmonella Gallinarum*. The incidence of fowl typhoid is low in the USA, Canada, and some European countries but is much higher in other countries. Although *S Gallinarum* is egg-transmitted and produces lesions in chicks and poults similar to those produced by *S Pullorum*, there is a much greater tendency to spread among growing or mature flocks. Mortality in young birds is similar to that seen in *S Pullorum* infection but may be higher in older birds.

Clinical Findings and Lesions: The disease may be acute or chronic. Clinical signs and lesions in young birds are similar to those seen with *S Pullorum* infection. Older birds may be pale, dehydrated, and have diarrhea. Lesions in older birds may include a swollen, friable and often bile-stained liver, with or without necrotic

foci; enlarged spleen and kidneys; anemia; and enteritis.

Diagnosis: Diagnosis should be confirmed by isolation, identification, and serotyping of *S Gallinarum* (National Poultry Improvement Plan testing procedure).

Treatment and Control: Treatment and control are as for pullorum disease (*see above*). There are no federally licensed vaccines in the USA. In other countries, vaccines (killed or modified live) made from a rough strain of *S Gallinarum* (9R) had variable results in controlling mortality. More recently, vaccines derived from outer membrane proteins, mutant strains, and a virulence-plasmid-cured derivative of *S Gallinarum* have shown promise in protecting birds against challenge. The standard serologic tests for pullorum disease are equally effective in detecting fowl typhoid.

PARATYPHOID INFECTIONS

Etiology: Paratyphoid infections can be caused by any one of the many non-host-adapted salmonellae. These *Salmonella* infect many types of birds, mammals, reptiles, and insects. Paratyphoid infections are of public health significance via contamination and mishandling of poultry products. *S Typhimurium*, *S Enteritidis*, *S Kentucky*, *S Heidelberg*, *S Hadar*, and *S Saintpaul* are among the most common *Salmonella* infections in poultry. Some serotypes are more pathogenic than others. The prevalence of other species varies widely by geographic location.

Transmission usually occurs horizontally from infected birds, contaminated environments, or infected rodents. Except for *S Enteritidis* and *S Arizonae*, transmission of most serotypes to progeny from infected breeders is mainly through fecal contamination of the eggshell. *S Enteritidis* and *S Arizonae* can infect the interior of the egg through transovarial transmission. Infected birds remain carriers.

Clinical Findings and Lesions: Although not common, clinical signs are sometimes seen in young birds. Mortality is most often limited to the first few weeks of age. Depression, poor growth, weakness, diarrhea, and dehydration are hallmarks of the disease, although these clinical signs are not distinctive.

Lesions may include an enlarged liver with focal necrosis, unabsorbed yolk sac,

enteritis with necrotic lesions in the mucosa, and cecal cores. Infections occasionally localize in the eye or synovial tissues. Conversely, there may be no lesions due to acute death caused by septicemia. Isolation, identification, and serotyping of the causal agent are essential for diagnosis. Serology is not highly reliable.

Treatment and Control: General control measures for the paratyphoid *Salmonella* include strict sanitation in the hatchery, fumigation of hatching eggs, pelleting of feed, cleaning and disinfection of poultry houses, rodent control, and use of competitive exclusion products. Maintenance of poultry in confinement and exclusion of all pets, wild birds, and rodents help prevent introduction of infection. The use of antibiotics is highly debated. Several antibacterial agents help prevent mortality but cannot eliminate flock infection and may lead to drug resistance. Vaccination with live or killed products has been used. Complete protection is not afforded by

vaccination, and it should be used in combination with other control measures to reduce the incidence of *Salmonella* infection.

S Enteritidis (a paratyphoid *Salmonella* serotype) is a major food safety concern primarily for the egg-laying industry. Possible sources in commercial layers include transmission from breeders, contaminated environments, infected rodents, and contaminated feed. Transmission to progeny from breeders is mainly through eggshell contamination, although, unlike other paratyphoid *Salmonella*, transovarial transmission may also occur. The National Poultry Improvement Plan includes *S* Enteritidis control measures in breeders, including depopulation of infected breeder flocks, cleaning and disinfection of pullet and layer houses, rodent control programs, pest management, feed management, use of competitive exclusion products, vaccination, biosecurity, and proper handling and refrigeration of eggs.

STAPHYLOCOCCOSIS

Staphylococcosis is a bacterial disease that can affect a wide range of avian species, including poultry, and is seen worldwide. *Staphylococcus aureus* is most commonly isolated from staphylococcosis cases, but species such as *S. hyicus* have also been reported as the causative agent of osteomyelitis in turkey poults. The disease conditions associated with staphylococcosis vary with the site and route of inoculation and can involve the bones, joints, tendon sheaths, skin, sternal bursa, navel, and yolk sac. Economic losses may result from decreased weight gain, decreased egg production, lameness, mortality, and condemnation at slaughter.

Etiology: *S. aureus* is a gram-positive, catalase-positive, coccoid bacteria that appears in grape-like clusters on stained smears. *S. aureus* is the most common isolate recovered from clinical cases. Most pathogenic strains have been coagulase-positive; however, coagulase-negative *Staphylococcus*, including *S. hyicus*, *S. epidermidis*, and *S. gallinarum* have been reported from clinical cases. Phage typing

has been used to distinguish among the different strains. *Staphylococcus* toxins can enhance the pathogenicity of a strain.

Transmission, Epidemiology, and Pathogenesis:

Because *Staphylococcus* is part of the normal skin and mucosal flora, many infections are the result of a wound, mucosal damage, or both. Infection can also occur in the hatchery as a result of contamination of an open navel. Birds that are immunocompromised are also more prone to staphylococcal infections. Once in the host, *S. aureus* invades the metaphyseal area of the nearest joint, which leads to osteomyelitis and localization within that joint. Alternatively, the bacteria can invade the bloodstream and lead to a systemic infection in multiple organs.

Clinical Findings: Omphalitis, or infection of the yolk sac, caused by *S. aureus* has been reported in young chicks and poults (see p 2859). Its prevalence depends on its presence in the breeder flock and the hatchery environment. Navel infections can occur in young hatchlings if the navel

becomes infected with *Staphylococcus*. Gangrenous dermatitis can occur after skin trauma and subsequent contamination with *Staphylococcus*. Immunocompromised birds have a higher prevalence of gangrenous dermatitis. Because *Staphylococcus* is found on the skin, skin injuries can also lead to localized abscesses, such as on the foot (bumblefoot). Finally, *Staphylococcus* can be dispersed systemically and can cause arthritis, synovitis, osteomyelitis, and endocarditis. Most *Staphylococcus* infections in poultry cause synovitis, with lameness being the most common clinical presentation. The bones and associated joints most frequently affected are those of the leg, especially the stifle and tibiotarsus. In addition, septicemia can result in green livers or livers with multifocal necrosis and/or granulomas. In acute infections, a sudden increase in mortality may be noted.

Lesions: Chicks with omphalitis have navels that are moist and dark, and affected birds are often lethargic. Infected yolk sacs are retained longer than uninfected yolk sacs, which are normally resorbed by the developing chick within the first week of life. Infected yolks are abnormal in color (dark green to brown), have a doughy consistency, and are odorous. Gangrenous dermatitis is often reported in immunocompromised chickens and is often due to a combination of *S aureus* and *Clostridium septicum* and/or *Escherichia coli*. Affected areas are usually hemorrhagic and crepitant. Lesions associated with septicemia are most common. Within the musculoskeletal system, affected bones often have focal yellowish areas of necrosis, while lesions in the joints contain purulent exudate. At the processing plant, green liver has been reported in turkeys that have had osteomyelitis and synovitis. Liver spots and granulomas resulting from septicemia have been a cause of liver condemnation. In acute infections, necrosis and vascular congestion are seen in the liver, spleen, kidneys, and other internal organs. Vegetations on the heart valves have been reported.

Diagnosis: Although some lesions may be suggestive of a *Staphylococcus* infection, diagnosis is confirmed by identifying the organisms from stained smears of the lesion and by culture on blood agar plates. Phenotyping and genetic techniques have been used to classify strains of poultry *S aureus*. Differential diagnoses include *E coli* and *Pasteurella multocida* as well as other septicemic diseases of poultry.

Treatment and Prevention: Staphylococcosis can be successfully treated with antibiotics, but an antimicrobial susceptibility test should be performed because antibiotic resistance is common. Antibiotics used to treat *Staphylococcus* infections include penicillin, erythromycin, lincomycin, and spectinomycin. Proper management to prevent injury and immunocompromised poultry helps prevent staphylococcosis. Because wounds are the primary route by which *Staphylococcus* can enter the body, it is important to reduce all potential sources of injury to the bird. Wood splinters in litter, protruding wires from cages, and fighting/cannibalism have been associated with skin wounds and staphylococcosis. Because beak and toe trimming procedures in young chickens and turkeys could result in a staphylococcal septicemia, ensuring that equipment is sanitary will help to prevent outbreaks. Good litter management is important in controlling foot-pad injuries to prevent bumblefoot. Hatchery sanitation and good egg management practices are also important to reduce navel infections and omphalitis.

Zoonotic Risk: *S aureus* can cause food poisoning in people. Enterotoxin-producing strains are found on clinically healthy poultry, and proper precautions should be taken during the handling and cooking of poultry products. Methicillin-resistant *S aureus* (MRSA) has been isolated from poultry meat in a number of countries, but the prevalence and significance for human health are incompletely understood.

STREPTOCOCCOSIS

Streptococcosis has been reported in numerous bird species throughout the world. There are two forms of the disease, an acute septicemic form and a chronic

form. Flock mortality can be as high as 50%. Because streptococci are part of the normal flora of the intestinal mucosa of most avian species, infections are often

thought to occur secondarily to other diseases.

Etiology and Epidemiology: Streptococci are nonmotile, gram-positive, catalase-negative coccoid bacteria that occur singly, in pairs, or in short chains when observed on stained smears. *Streptococcus* spp commonly associated with disease in avian species include *S zooepidemicus* (*S gallinarum*), *S bovis*, *S dysgalactiae*, *S gallinaceus*, and *S mutans*. Streptococci have been associated with acute septicemia, joint infections, cellulitis, osteomyelitis, and endocarditis. Transmission is via oral or aerosol routes as well as through skin injuries.

Clinical Findings: Streptococcal infections can be localized or septicemic. Endocarditis and lameness occur during the subacute or chronic stage of the infection. In *S zooepidemicus* infections, clinical signs are typical of an acute septicemic infection, and lethargic birds are often prostrate. In affected layers, egg production may drop by 15%. In pigeons, *S bovis* infection produces acute mortality with lameness, inappetence, diarrhea, and the inability to fly. Acute fibrinopurulent conjunctivitis has been noted in infections caused by other *Streptococcus* spp.

Lesions: Lesions in the acute septicemic form include splenomegaly, hepatomegaly (with or without reddish tan to white multifocal necrotic foci), and enlarged kidneys. There may also be serosanguineous fluid in the subcutaneous space and in the pericardium. Bloodstained feathers around the mouth and head due to blood from the oral cavity have been reported occasionally. Cellulitis involving the skin and subcutaneous tissues has been associated with both *Escherichia coli* and *S dysgalactiae*.

Chronic streptococcal infections result in arthritis and/or tenosynovitis, osteomyelitis,

salpingitis, pericarditis, myocarditis, and valvular endocarditis. Lesions on the heart valves appear as small yellowish white or tan raised areas on the valvular surface. Focal granulomas, as a result of septic emboli, can be found in many tissues. Gram-positive bacterial colonies are readily observed in thrombosed vessels and within necrotic foci microscopically.

Diagnosis: History, clinical signs, and lesions, along with demonstration of *Streptococcus*-like bacteria in blood films or impression smears of affected tissues, allows for a presumptive diagnosis of streptococcosis. Isolation of *Streptococcus* spp from lesions confirms the diagnosis. Streptococci can be cultured easily on blood agar.

Differential diagnoses include other bacterial septicemic diseases, including staphylococcosis, enterococcosis, colibacillosis, pasteurellosis, and erysipelas. Infectious laryngotracheitis, pasteurellosis, avian influenza, and exotic Newcastle disease should be considered as differential diagnoses when blood is noted coming from the mouth.

Treatment and Control: Antibiotics, including penicillin, erythromycin, novobiocin, oxytetracycline, chlortetracycline, and tetracycline, have been used to treat acute and subacute infections. Clinically affected birds respond well early in the course of the infection, but this response decreases as the disease progresses within a flock. Antimicrobial susceptibility testing should be performed to select a suitable antibiotic.

Because streptococcosis often occurs secondary to other diseases, it is important to prevent immunosuppressive diseases and conditions. In addition, because skin wounds can provide an entry for *Streptococcus*, it is important to reduce this risk factor. Proper cleaning and disinfection can reduce environmental sources of infection.

TUBERCULOSIS

Tuberculosis is a slowly spreading, chronic, granulomatous bacterial infection characterized by gradual weight loss. All birds appear to be susceptible, although to variable degrees; pheasants seem to be highly susceptible, whereas the disease is uncommon in

turkeys. Tuberculosis is more prevalent in captive than in free-living wild birds. It is unlikely to be seen in commercial poultry because of the short life span and husbandry practices used. (See also TUBERCULOSIS AND OTHER MYCOBACTERIAL INFECTIONS, p 687.)

Etiology and Epidemiology: *Mycobacterium avium* ss is the most common cause, although *M. genavense* has been isolated from some psittacine birds. Seroagglutination tests of isolates are recommended to differentiate strains of *M. avium* that cause disease in chickens and birds from those that fail to produce disease in these species. *M. tuberculosis*, the cause of tuberculosis in people, has infrequently been isolated from parrots and canaries. *M. avium* is very resistant; it can survive in soil for ≥ 4 yr, in 3% hydrochloric acid for ≥ 2 hr, and in 2% sodium hydroxide for ≥ 30 min.

Tuberculosis is found worldwide, most commonly in small, barnyard flocks and in zoo aviaries; it is rarely found in young flocks. Wild birds, such as cranes, sparrows, starlings, and raptors, have been found to be infected. Tuberculosis has been found in emus and other ratites. The movement of ratites through sales and the long life of these animals have made tuberculosis a major concern for ratite producers. Isolation of ratites purchased at sales is essential to prevent the introduction of tuberculosis into established flocks.

Infected birds with advanced lesions often excrete the organism in their feces; therefore, ingestion of contaminated feces is the most common route of transmission. Carcasses and offal may infect predators and cannibalistic flock mates. Rabbits, pigs, nonhuman primates, and mink are readily infected. Cattle exposed to contaminated feces may develop granulomatous lesions in lymph nodes associated with the GI tract and respond to *M. bovis* purified protein derivative (PPD) tuberculin and to PPD of *M. avium*. *M. avium* serovar 1 is often isolated from tuberculous free-living wild birds and birds in captivity. *M. avium* ss and *M. genavense* have been isolated from immunocompromised people; however, these organisms only rarely cause disease in nonimmunocompromised individuals.

Clinical Findings and Diagnosis: Signs usually do not develop until late in the infection, when birds become emaciated and sluggish and lameness may be seen. In chickens, granulomatous nodules of varying size are often found in the liver, spleen, bone marrow, and intestine. Some exotic species may have lesions in the liver and spleen without intestinal or bone marrow involvement. Small mesenteric nodules may be found. Lesions are not mineralized.

Live birds may be tested with *M. avium* PPD tuberculin, although these tests are of limited value in birds that do not have wattles (it is often difficult to inject tuberculin intradermally because of skin thickness at other sites). A test conducted in skin on the underside of the wing has been used in Japanese quail exposed to *M. avium*. The injection site is observed at 24 and 48 hr for induration and swelling. A positive test indicates exposure to *M. avium*; however, a negative test is of little or no significance. Large numbers of acid-fast bacteria in smears from lesions provide a tentative diagnosis. Mycobacteriologic examination is required to confirm a diagnosis. Isolates can be identified based on biochemical, drug susceptibility, and seroagglutination tests and by restriction length polymorphism analyses.

Prevention and Control: Addition of exotic birds to an exhibit should originate from a closed collection with no history of tuberculosis, ie, tuberculosis has not been reported previously or diagnosed on necropsy during the past 5 yr. If no history is available, the birds should be quarantined or maintained in a separate exhibit away from the bird aviary. Transmission is by ingestion of food or water contaminated with *M. avium* ss, ie, feces from contagious birds. Therefore, it is recommended that endangered and valuable species be housed in individual exhibits.

Chemotherapy is ineffective, because most *M. avium* complex organisms are resistant to antituberculosis drugs. In commercial poultry flocks, relatively rapid turnover of populations, together with improved general sanitation, has largely eliminated this once common infection. Infected poultry should be destroyed, and housing facilities thoroughly cleaned and disinfected using cresylic compounds. Quaternary ammonium compounds and halogens (eg, chlorine) do not effectively kill mycobacteria. In exhibits with dirt floors, several inches of the floor should be removed and replaced with dirt from a place where poultry have not been maintained. All openings should be screened against wild birds.

Avian tuberculosis in zoos is difficult to eradicate. New additions to the aviary should be quarantined for ≥ 6 mo. Isolation and quarantine of birds of unknown status purchased at sales is essential to prevent introduction of tuberculosis into established flocks.

TURKEY VIRAL HEPATITIS

Turkey viral hepatitis is an acute, highly contagious, frequently subclinical disease of turkey poults 5 wk of age. The disease is widespread and common in some areas, with morbidity rates of as much as 100%. Mortality has been reported only in poults, is confined to a 4- to 8-day period, and may reach 25%.

Etiology: A picorna-like virus from poults with typical lesions has been reported, but its etiologic role has not been conclusively established. The causal virus has not been fully classified, but a picornavirus from turkeys with typical lesions of turkey viral hepatitis has been molecularly characterized and proposed as a new species in the order Picornavirales. It is isolated without difficulty from the liver and a variety of other tissues, including the pancreas, spleen, and kidney, as well as feces. The virus is isolated less consistently from older birds. It grows readily in the yolk sac of 5- to 7-day-old chicken or turkey embryos. It is thermostable; resistant to ether, phenol, and creolin but not formalin; and susceptible to high, but not low, pH.

Clinical Findings: Disease is usually subclinical and becomes apparent only when the birds are stressed. Affected birds are stunted and unthrifty. Morbidity and mortality vary according to the severity of stress. In poults <5 wk old, morbidity may reach 100% and mortality 10%-25%. Breeder flocks may exhibit decreased production, fertility, and hatchability.

Lesions: Gross lesions are confined to the liver and pancreas. In the liver, foci of necrosis are 1-3 mm in diameter and may

be confluent. Areas of hemorrhage or congestion are also present and frequently obscure the degenerative changes. Occasionally, the liver is diffusely bile-stained. Liver lesions may resemble those of bacterial infections, particularly from *Salmonella* spp, *Pasteurella multocida*, or *Escherichia coli*, and infections caused by Group 1 and Group 2 avian adenovirus and reovirus. The pancreas frequently exhibits relatively large, circular, gray areas of degeneration. In the subclinical form, lesions are less extensive, and hepatic hemorrhage or congestion is seldom prominent. Affected tissues return to normal in 3-4 wk.

Diagnosis: *Salmonella* spp and other bacterial infections produce necrotic areas in the liver that can be confused with those of viral hepatitis. Bacterial infections must be differentiated by appropriate culturing techniques. Liver lesions may resemble those of histomoniasis, but the absence of cecal lesions in turkey viral hepatitis helps to differentiate the two diseases. With histomoniasis, histologic examination or demonstration of the respective etiologic agents is necessary. Diagnosis is aided by demonstration of picornavirus by immunohistochemical or molecular techniques from poults with typical lesions.

Control: There is no known treatment. Secondary bacterial invasion does not appear to be important, but if it occurs, it should be treated on the basis of specific etiology. Although recovered birds demonstrate resistance to infection, neutralizing antibodies have not been detected. Improved sanitation may be of value in preventing dissemination of the agent.

MISCELLANEOUS CONDITIONS OF POULTRY

ASCITES SYNDROME

(Pulmonary hypertension syndrome, Waterbelly)

Ascites is an accumulation of noninflammatory transudate in one or more of the peritoneal cavities or potential spaces. The

fluid, which accumulates most frequently in the two ventral hepatic, peritoneal, or pericardial spaces, may contain yellow protein clots. Ascites may result from increased vascular hydraulic pressure, vascular damage, increased tissue oncotic pressure, or decreased vascular oncotic (usually colloidal) pressure, but is most

commonly associated with venous hypertension resulting from right heart failure to increased pulmonary resistance.

The most common cause of ascites is increased vascular hydraulic pressure in the venous system, which is most commonly caused by right ventricular failure (RVF), also associated with hepatic fibrosis. It is well documented that most cases are caused by a genetic predisposition to pulmonary hypertension, which progresses to congestive heart failure and terminal ascites in many cases.

Pulmonary hypertension occurs frequently in chickens secondary to high altitude-associated hypoxia with resultant polycythemia and increased blood viscosity. It also occurs frequently secondary to the RBC rigidity of sodium toxicity and less frequently from lung pathology. When ascites occurs at low altitudes in meat-type chickens, which have a high metabolic oxygen requirement, it is usually caused by primary or spontaneous pulmonary hypertension because of insufficient capacity of the pulmonary capillaries. Cold stress, even briefly, during the first 3 wk of life is known to markedly increase predisposition to ascites syndrome.

In poultry, liver damage may be caused by aflatoxin or by toxins from plants such as *Crotalaria*. In broiler chickens, obstructive cholangiohepatitis (caused by *Clostridium perfringens* infection) is the most common cause of the liver damage, which results in ascites. In both meat-type ducks and breeders, amyloidosis of the liver may also cause ascites.

Pathogenesis and Epidemiology:

Pulmonary hypertension syndrome is caused by increased pressure in the pulmonary arteries when the heart tries to pump more blood through the lungs to meet the body's oxygen requirement. The resultant volume and pressure overload on the right ventricle cause dilatation and hypertrophy of the right ventricular wall, valvular insufficiency, RVF, and ascites.

Bird lungs are rigid and fixed in the thoracic cavity. The capillaries can expand very little to accommodate increased blood flow. Lung size in proportion to body weight, and particularly to muscle mass, decreases as meat-type chickens grow. Increased blood flow results in primary pulmonary hypertension and cor pulmonale with sporadic cases of RVF and ascites in fast-growing broilers. Predisposing factors that increase oxygen demand (eg, cold), reduce oxygen-carrying capacity of the

blood (eg, acidosis, carbon monoxide), increase blood volume (eg, sodium), or interfere with blood flow through the lung (eg, lung pathology that narrows or occludes capillaries, increased RBC rigidity, or polycythemia with increased blood viscosity) may result in flock outbreaks of pulmonary hypertension syndrome with or without ascites.

The incidence of pulmonary hypertension syndrome is >2% in some broiler and many roaster flocks and is occasionally 15%–20% in other roaster flocks. Right ventricular hypertrophy is the response to an increased workload and eventually leads to RVF if the volume or pressure load persists. Hypertrophy and dilatation of the right ventricular wall is directly related to pulmonary hypertension, and the ratio of the right ventricle to the total ventricular mass can be used as a measure of the increased pressure load on the right ventricle.

Clinical Findings: Occasionally, young broilers develop pulmonary hypertension syndrome, particularly if increased sodium or lung pathology (eg, aspergillosis) is involved, but mortality is greatest after 5 wk of age. There are no signs until RVF occurs and ascites develops. Clinically affected broilers are cyanotic, the abdominal skin may be red, and peripheral vessels congested. Because growth stops as RVF develops, affected broilers may be smaller than their pen mates. However, rapid growth rate is a known predisposing factor, and sometimes the largest broilers are affected, with occurrence in males more frequent than in females. The ascites increases the respiratory rate and reduces exercise tolerance. Affected broilers frequently die on their backs. Not all broilers that die from pulmonary hypertension syndrome have ascites. Death may occur suddenly before signs are seen.

Lesions: Most lesions are the result of increased venous hydraulic pressure secondary to RVF. There is a variable amount of clear yellow fluid and clots of fibrin in the hepatoperitoneal spaces. The liver may be swollen and congested, or firm and irregular with edema, and have clotted protein adherent to the surface. It may be nodular or shrunken; it may be white with subcapsular edema and a thickened capsule or have large or small blebs of fluid between the capsule and the visceral peritoneum. Hydropericardium is mild to marked, and occasionally there is pericarditis with adhesions, usually from secondary

infections. Right ventricular dilatation and mild to marked hypertrophy of the right ventricular wall may be noted. The right atrium and vena cava are markedly dilated in most cases. Occasionally, there is thinning of the left ventricle. The lungs are extremely congested and edematous. The intestine may or may not be empty.

Diagnosis: Broilers that die from ascites or suddenly as the result of RVF or pulmonary hypertension can be identified by the enlarged heart; enlarged, thickened right ventricle; or fluid in the body cavities and heart sac. If the wall of the right ventricle is enlarged or thickened, the broiler has probably died from pulmonary hypertension syndrome, even if there is no fluid in the body or heart sac.

Control: Reducing the birds' metabolic oxygen requirement by slowing growth or reducing feed density or availability can prevent ascites caused by pulmonary hypertension syndrome. Environmental temperature, humidity, and air movement should be controlled to prevent excessive loss of body heat, particularly in the early neonatal period. Even brief exposure to cold stress during the first weeks of life is known to predispose flocks to this condition. Ascites caused by other factors (eg, sodium, lung damage, liver damage, etc) can be prevented by avoiding the etiologic agents involved. Altitudes >3,000 ft (900 m) are unsatisfactory for meat-type chickens, and growth must be slowed to prevent mortality. More care to prevent chilling is also necessary at higher altitudes. Research has demonstrated that broilers can be genetically selected for both resistance and susceptibility to pulmonary hypertension syndrome and associated ascites.

BREAST BLISTERS

In chickens and turkeys, a bursa lined with synovial membrane is normally present over the anterior projection of the keel bone. When this bursa becomes inflamed by trauma or infection, fluid accumulates and appears as a fluid-filled blister 1–3 cm in diameter. Factors in trauma to the bursa include poor feathering, hard flooring, and leg weakness, which is associated with increased time of sitting on the keel (sternum). Coarse bedding materials or wet litter conditions are predisposing factors and should be corrected when identified. Infectious causes of sternal bursitis include *Mycoplasma synoviae*, *Staphylococcus*, and *Pasteurella* spp, either from local

trauma (*Staphylococcus*) or as an extension of a systemic infection.

BREAST BUTTONS

Breast buttons develop in a location similar to that of breast blisters (see above). They have a localized, hard crust on the surface and a core of dead skin and chronic inflammation extending into the subcutis. The cause is not well defined, but a breast button may start as a chemical burn due to prolonged contact of poorly feathered skin with wet litter containing ammonia or toxins. The presence of good quality, dry litter is associated with a reduced number of affected turkeys.

CANNIBALISM

Cannibalism stems from aggressive behavior of chickens and turkeys that may begin by feather pecking by socially dominant birds. It may also involve vent pecking immediately after oviposition, or picking at skin on the head, comb, wattles, or toes. No single cause has been identified, but crowding, excessive light intensity, and nutritional imbalances are correlated with its occurrence. Additionally, in overweight pullets entering egg production or hens in production, mucosa will protrude from the vent during and after egg laying, and this red tissue attracts pecking. Other factors are insufficient feeder space, mineral and vitamin deficiencies, skin injuries, and failure to remove any dead birds daily. In addition to the loss of birds due to pecking trauma, cannibalism often leads to transmission of infectious diseases (eg, erysipelas) and botulism.

Control depends on correcting or reducing the above risk factors. Interventions include correcting an inadequate diet, replacing mash feed with pelleted feed, rearing birds on floor litter rather than slats, reducing light intensity, and providing perches as a refuge for targeted birds. Environmental enrichment such as hanging white or yellow strings may be beneficial. Trimming the sharp distal end (tip) of the upper beak will decrease skin trauma from pecking; this may be done at 1 day of age and repeated between 6 and 12 wk of age in maturing pullets or turkeys. The tip of the beak can also be treated by infrared heat on the day of hatching, which results in a shortened beak with minimal stress. Cauterization is required to provide hemostasis during beak trimming in older poultry.

FLUKE INFECTIONS

Modern poultry housed indoors are essentially free of flukes, because all flukes require a snail as an intermediate host and often require a third invertebrate host. However, these parasites persist in backyard poultry (see p 1815), which may have contact with snails or other hosts and wild birds. The trend toward free-range rearing of poultry may increase the exposure of poultry to this type of parasite, but flukes are mainly reported in wild birds with low prevalence.

Prosthogonimus macrorchis, the oviduct fluke of poultry, infects birds after they consume infective metacercariae in larval or mature dragonflies, the secondary host. The fluke matures in ~2 wk in the bursa of Fabricius or, in gallinaceous birds without a functional bursa (eg, chickens, turkeys, pheasants), in the oviduct.

Light infections without signs appear in ducks and other birds with a functional bursa. In gallinaceous birds, heavy infections in the oviduct cause inappetence, droopiness, weight loss, calcareous cloacal discharge, depressed egg production, and an increase in soft-shelled eggs. Lesions range from mild inflammation to distention or rupture of the oviduct; death may result. Diagnosis by fecal examination is unreliable, because fluke eggs are not consistently present. Adult flukes may appear in the bird's eggs or be found in the oviduct on necropsy.

To prevent fluke transmission, birds must be kept from feeding on dragonflies. There is no effective treatment approved for use in poultry. Carbon tetrachloride, a common remedy, is highly toxic to chickens and other birds.

Collyricium faba, another common fluke in birds, appear as subcutaneous cysts 4–6 mm in diameter (usually containing two adults) anywhere on the body but more frequently near the vent in turkeys, chickens, and other birds. The cysts ooze an exudate, which attracts flies and predisposes to bacterial infection. Signs in young birds include locomotor difficulty and inappetence; heavy infections may cause death. The parasites can be removed surgically. The life cycle is unknown but probably involves snails and insects such as dragonflies or mayflies. Prevention of infection requires restricting birds from bodies of water and areas frequented by aquatic insects.

PENDULOUS CROP

Incidence of pendulous crop is low in flocks of chickens but appears to be increasing in

turkeys. The crop is grossly distended and contains foul-smelling fluid, feed, and litter. Feed utilization is impaired, and severely affected birds become thin or emaciated. Survivors often are condemned or trimmed at processing to reduce contamination by crop contents.

The cause is not known, but a hereditary predisposition, potentially associated with hyperphagia, has been suggested in turkeys. Incidence may increase with erratic or excessive feed or water consumption. Vagus nerve damage has also been postulated as a cause in rare cases. There is no known efficacious treatment.

URATE DEPOSITION (GOUT)

Avian species excrete nitrogenous wastes as urates bound in colloidal form with mucus in their urine. Renal dysfunction decreases the clearance of uric acid from the blood, which results in hyperuricemia with precipitation of insoluble products within the kidney itself or other organs, leading to urate deposition or urolithiasis (gout). Urate deposits are white and semisolid and must be differentiated from yellow fibrinous or purulent inflammatory exudates that are secondary to infectious causes, such as synovitis, peritonitis, perihepatitis, and pericarditis.

Visceral urate deposition occurs after rapidly progressing renal failure, or as a terminal event with acute decompensation of chronic renal disease. Deposits develop most commonly on the pericardium, peritoneum, and liver capsule, and rarely on synovial surfaces of joints and tendons. Microscopically, urate deposits are often seen as feathery crystals or basophilic spherical masses, usually with little inflammation due to the rapid course. Visceral urate deposition may be secondary to **urolithiasis**, which is common in older laying chickens. Progressive obstruction of the ureters by uroliths causes kidney atrophy "upstream" of the site of uretral obstruction and compensatory hypertrophy by the undamaged portions of the kidney. Distended ureters often contain brittle, white, staghorn calcium urate calculi or uroliths.

Predisposing factors for visceral urate deposition and urolithiasis in poultry include infectious bronchitis virus, avian nephritis virus, and cryptosporidiosis. Noninfectious causes include dehydration, ingestion of feed containing >3% calcium by nonlaying chickens, vitamin A deficiency, and exposure to mycotoxins (eg, oosporein). Other avian species commonly

develop visceral deposits secondary to nephrotoxin exposure, most commonly aminoglycoside antibiotics or heavy metals.

Articular urate deposition is less common and occurs after longterm increases in serum levels of uric acid.

Deposits develop on synovial membranes in the toes and wing joints and incite a chronic granulomatous reaction to urate crystals (tophi). Articular urate deposition may be seen in birds that have hereditary defects in uric acid metabolism or that are fed excessive protein.

ECTOPARASITES

BEDBUGS

Cimex lectularius is a common bloodsucking parasite in temperate and subtropical climates that attacks poultry, people, and most other mammals. It is rare in modern laying operations, but breeding houses and pigeon lofts may become heavily infested. The life cycle may be completed in 2–6 wk or extend much longer, because nymphs can withstand fasting for ~70 days, and adults for as long as 12 mo. Feeding usually occurs at night. Bedbugs become engorged within 10 min, then hide in cracks and crevices. If attacked by large numbers of bedbugs, birds may become irritable and anemic. Bites are usually followed by swelling and itching due to injection of saliva into the wound. Signs of infestation include bug fecal droppings on eggs and nest boxes, breast and leg skin lesions, reduced egg production, and increased feed consumption.

Control is best accomplished by thoroughly cleaning the houses, reducing hiding places for the bedbugs, and fumigating the houses with organophosphates or pyrethroids that remain on surfaces providing access to hosts.

FLEAS

The **sticktight flea**, *Echidnophaga gallinacea*, is a major poultry pest in the subtropical and tropical New World. It is unique among poultry fleas in that the adults become sessile parasites and usually remain attached to the skin of the head or anus for days or weeks. The adult females forcibly eject their eggs so that they reach surrounding litter. The larvae develop best in sandy, well-drained litter. Hosts of the adult flea include chickens, turkeys, pigeons, pheasants, quail, people, and many other mammals. Fleas cause irritation, restlessness, and blood loss that results in anemia

and death, particularly in young birds. Bites around the eyes can cause ulcerations, resulting in blindness.

The **Western chicken flea**, or **black hen flea**, *Ceratophyllus niger*, seems to be confined to the Pacific coast area of the USA and Canada. This flea breeds in droppings and feeds on birds only occasionally. The **European chicken flea**, *C. gallinae*, is found worldwide. It breeds in nests and litter and is on the birds only to feed. In addition to chickens, it attacks many other birds as well as people and domestic pets. Heavy flea infestations cause host emaciation and reduced egg production.

The most important flea control measures are removing infested litter and dusting the litter surface with carbaryl, coumaphos, malathion, or pyrethroids to kill immature fleas. Insect growth regulators such as methoprene are also effective. Sticktight fleas can be controlled by topical application of pyrethrin.

FLIES AND GNATS

Biting Midge

Culicoides spp (Ceratopogonidae) feed on blood and transmit blood parasites to birds. They are vectors for transmission of *Haemoproteus* to ducks and geese in Canada and turkeys in North America, and of *Leucocytozoon* to chickens in Southeast Asia and Japan. They also transmit the skin mite *Myialges anchora* (Epidermoptidae). Bites are reddish and itch for as long as 3 days. Midges feed at twilight or night, and typical mesh screens do not keep them out. Pyrethroid insecticides can provide temporary control.

Black Fly

Simulium spp (Simuliidae), also known as buffalo gnats and turkey gnats, are

bloodsuckers and transmit leucocytozoosis (see p 2783) to ducks, turkeys, and other birds. They are most abundant in the north temperate and subarctic zones, but many species are found in tropical areas. They often attack in swarms and cause weight loss, reduced egg production, anemia, and death of birds either directly or through disease transmission. Control is extremely difficult because immature stages are restricted to running water, which is often some distance from the poultry farm. Larval control can be achieved with applications of *Bacillus thuringiensis israelensis* during early spring before adults emerge. Chemical larvicides such as temephos and methoxychlor can also be used. Screens of 24 mesh per in. (2.54 cm) or smaller are required for adult control. However, black flies rarely enter shelters.

Pigeon Fly

The pigeon fly, *Pseudolynchia canariensis* (Hippoboscidae), is an important blood-sucking parasite of pigeons in warm or tropical areas. It can transmit the blood parasites *Haemoproteus* and *Trypanosoma*, the skin mite *Myialges anchora* (Epidemiptidae), and pigeon lice (*Columbicola columbae*). It may also cause heavy losses in squabs. The pigeon loft should be cleaned every 20 days, and squabs can be dusted with permethrin or deltamethrin.

FOWL TICKS

The fowl tick, *Argas persicus*, is found worldwide in tropical and subtropical countries and is the vector of *Borrelia anserina* (avian spirochetosis, see p 2813) and the rickettsia *Aegyptianella pullorum*, which causes fowl disease (aegyptianellosis, see p 2780). In the USA, the *Argas persicus* complex has been divided to include *A. miniatus*, *A. sanchezi*, and *A. radiatus* in addition to *A. persicus*. These ticks are particularly active in poultry houses during warm, dry weather. All stages may be found hiding in cracks and crevices during the day. Larvae can be found on the birds, because they remain attached and feed for 2–7 days. Nymphs and adults feed at night for 15–30 min. Nymphs feed and molt several times before reaching the adult stage. Adults feed repeatedly, most commonly under the wings, and the females lay as many as 500 eggs after each feeding. Adult females may live >4 yr without a blood meal.

Fowl ticks produce anemia (most important), weight loss, depression,

toxemia, and paralysis. Egg production decreases. Red spots can be seen on the skin where the ticks have fed. Because the ticks are nocturnal, the birds may show some uneasiness when roosting. Death is rare, but production may be severely depressed.

After houses are cleaned, walls, ceilings, cracks, and crevices should be treated thoroughly (using a high-pressure sprayer) with carbaryl, coumaphos, malathion, permethrin, stirofos, or a mixture of stirofos and dichlorvos. Cracks and crevices should be filled in.

LICE

Avian lice, which belong to the order Mallophaga, have a life cycle of ~3 wk and normally feed on bits of skin or feather products. Lice may live for several months on the host but only remain alive for ~1 wk off the host. People and other mammals may harbor avian lice, but only temporarily.

In intensive poultry systems, the most common and economically important louse to both chickens and turkeys is *Menacanthus stramineus*, the chicken body louse, which typically is found on the breast, vent, and thighs. It punctures soft quills near their base or gnaws the skin at the base of the feathers and feeds on the blood. Chickens are less commonly infested with *Menopon gallinae* (on feather shafts), *Lipeurus caponis* (mainly on the wing feathers), *Cuclotogaster heterographus* (mainly on the head and neck), *Goniocotes gallinae* (very small, in the fluff), *Goniodes gigas* (the large chicken louse), *Goniodes dissimilis* (the brown chicken louse), *Menacanthus cornutus* (the body louse), *Uchida pallidula* (the small body louse), or *Oxylipeurus dentatus*. Turkeys may also be infested with *Chelopistes meleagridis* (the large turkey louse), and *Oxylipeurus polytrapezius* (the slender turkey louse).

Because lice transfer from one bird species to another when the hosts are in close contact, other domestic and caged birds may be infested with species of Mallophaga that are usually host-specific. Lice also sometimes reach new bird hosts by using louse flies (Hippoboscidae) for transportation. Some lice of geese and swans are vectors of filarial nematodes.

Heavy populations of the chicken body louse decrease reproductive potential in males, egg production in females, and weight gain in growing chickens. The skin irritations are also sites for secondary bacterial infections. Other species of lice are not highly pathogenic to mature birds

but may be fatal to chicks. Examination of birds, particularly around the vent and under the wings, reveals eggs or moving lice on the skin or feathers.

Lice are usually introduced to a farm through infested equipment (eg, crates or egg flats) or by galliform birds. Lice are best controlled on caged chickens or turkeys by spraying with pyrethroids, carbaryl, coumaphos, malathion, or stirofos. Birds on the floor are more easily treated by scattering carbaryl, coumaphos, malathion, or stirofos dust on the litter. Eggs are not killed, so insecticide treatment should be repeated after 10 days.

MITES

The most economically important of the many external parasites of poultry are mites of the families Dermanyssidae (chicken mite, northern fowl mite, and tropical fowl mite) and Trombiculidae (turkey chigger).

Chicken Mite

(Red mite, Roost mite, Poultry mite)

Dermanyssus gallinae infests chickens, turkeys, pigeons, canaries, and various wild birds worldwide. These bloodsucking mites will also bite people. While rare in modern commercial cage-layer operations, it is found in breeder and small farm flocks. Chicken mites are nocturnal feeders that hide during the day under manure, on roosts, and in cracks and crevices of the chicken house, where they deposit eggs. Populations develop rapidly during the warmer months and more slowly in cold weather; the life cycle may be completed in only 1 wk. A house may remain infested for 6 mo after birds are removed.

Transmission of the chicken mite, as well as the northern fowl mite and the tropical fowl mite (see below), is by mite dispersion or by contact with infested birds, animals, or inanimate objects. In the integrated poultry industry, mites are dispersed most frequently on inanimate objects such as egg flats, crates, or coops or by personnel going from house to house or farm to farm.

Heavy infestations of either chicken mites or northern fowl mites decrease reproductive potential in males, egg production in females, and weight gain in young birds; they can also cause anemia and death. Chicken mites may be found in the chicken houses during the day, particularly in cracks or where roost poles touch supports, or on birds at night. Their role as vectors of other pathogens in nature needs study, but experimental transmission of

Eastern, Western, and Venezuelan equine encephalitis viruses, fowl poxvirus, and the bacteria *Salmonella* Enteritidis, *Pasteurella multocida*, *Coxiella burnetii*, and *Borrelia anserina* has been demonstrated.

Obtaining mite-free birds and using good sanitation practices are important to prevent a buildup of mite populations. Once poultry have been infested, control may be achieved by spraying or dusting the birds and litter with amitraz, carbaryl, coumaphos, malathion, stirofos, or a pyrethroid compound in areas where the parasites have not developed resistance to these chemicals. Miticide spray treatments must be applied with sufficient force to penetrate the feathers in the vent area. Nicotine sulfate is an effective fumigant for mites but is particularly hazardous. Pyrethrins and piperonyl butoxide are initially active but have poor residual killing power. For control of chicken mites, in addition to treating the birds, the inside of the house and all hiding places for the mite (such as roosts, behind nest boxes, and cracks and crevices) must be treated thoroughly using a high-pressure sprayer. Dinethoate and fenitrothion may be used as residual house sprays when poultry are not present. Inert dusts such as diatomaceous earth and pure synthetic amorphous silicas can be effective, but application rates need to be high when the humidity is very high. Systemic control with ivermectin (1.8–5.4 mg/kg) or moxidectin (8 mg/kg) is effective for short periods, but the high dosages are expensive, close to toxic levels, and require repeated use.

Common Chigger

The common chigger, *Trombicula alfreddugesi*, and other chigger species (harvest mites, red bugs) infest birds as well as people and other mammals, feeding on partially digested skin cells and lymph. Heavily parasitized birds become droopy, refuse to eat, and may die from starvation and exhaustion. Larvae may be found either singly or in clusters on the ventral portion of the birds. Control on the range is aided by keeping the grass cut short and dusting with sulfur, carbaryl, or malathion.

Depluming Mite

The depluming mite, *Neocnemidocoptes gallinae*, is found worldwide and burrows into the epidermis at the base of feather shafts, causing intense irritation and feather pulling and loss in chickens, pheasants, pigeons, and geese in spring and summer. Hyperkeratosis, skin lesions, and digit

necrosis can result from the burrowing. Affected birds should be isolated and treated with ivermectin, malathion, or sevin dust.

Feather Mite

Most feather mites belong to the families Analgidae, Pterolichidae, and Proctophylodidae. Surface feather mites feed mainly on feather oils, debris, fungi, and skin scales. More than 25 species, including *Megninia cubitalis*, *M. ginglymura*, and *Pterolichus obtusus*, are found on domestic poultry, but they are rare on modern poultry ranches. Quill mites (Syringophilidae and Gaudoglyphidae) live in quills and feed on quill tissue or fluids obtained by piercing the calamus wall. *Syringophilus bipectinatus* is found in chicken and turkey feather quills worldwide, and *Columbiphilus polonica*, *Dermoglyphus elongatus*, and *Gaudoglyphus minor* live in chicken quills in Europe. Feather mites do little economic damage but may reduce egg production via malnutrition, feather loss, and dermatitis. Affected birds should be dusted with pyrethrin or carbaryl powder, or oral or topical ivermectin can be applied.

Northern Fowl Mite

The northern fowl mite, *Ornithonyssus sylviarum*, is the most important parasite of caged layers and breeding chickens in the USA and is a serious pest of chickens throughout the temperate zone of other countries. On turkeys, it is second in importance only to the turkey chigger in areas where the turkey chigger is found. It has been reported from many species of birds and from rats, mice, and people; however, fertile populations are reported only on birds. Northern fowl mites are obligate bloodsucking parasites that normally spend their entire life cycle (~1 wk) on the host. Off the host, mites may live as long as 2 mo, depending on temperature and relative humidity. Northern fowl mites are found on eggs or by parting feathers in the vent area, which may have thick, crusty skin, severe scabbing, and soiled feathers.

Western equine encephalomyelitis, St. Louis encephalitis, and Newcastle disease viruses, as well as fowlpox virus, have been isolated from these mites. However, the mites are not significant vectors of these viruses. For clinical findings and control, see above.

Scaly Leg Mite

The scaly leg mite, *Knemidocoptes mutans*, is a small, spherical, sarcoptic mite that

usually tunnels into the tissue under the scales of the legs. It is rare in modern poultry facilities. When found, it is usually on older birds on which the irritation and exudation cause the legs to become thickened, encrusted, and unsightly. Feet and leg scales become raised, resulting in lameness. Birds stop feeding, and death can result after several months. This mite may occasionally attack the comb and wattles. The entire life cycle is in the skin; transmission is by contact. Infections can be latent for long periods until stress triggers a mite population increase.

For control, affected birds should be culled or isolated, and houses cleaned and sprayed frequently as recommended for the chicken mite (see above). Individual birds should be treated with oral or topical ivermectin or moxidectin (0.2 mg/kg), 10% sulphur solution, or 0.5% sodium fluoride.

Cyst Mite

Laminosioptes cysticola, the fowl cyst mite, is a small cosmopolitan parasite of chickens, turkeys, and pigeons that is most often diagnosed by observing white to yellowish caseocalcareous nodules ~1–3 mm in diameter in the subcutis, muscle, lungs, and abdominal viscera. Careful examination of the skin and subcutis of birds under a dissecting microscope frequently reveals the mites. Destroying the bird has been the best control for this parasite, but ivermectin may be effective.

Tropical Fowl Mite

The tropical fowl mite, *Ornithonyssus bursa*, is distributed throughout the warmer regions of the world and has been reported in Hawaii, Texas, Florida, Illinois, Indiana, Maryland, and New York. It closely resembles the northern fowl mite (see above) in its biology and habits but lays a greater proportion of its eggs in the nest. Hosts include chickens, turkeys, ducks, pigeons, sparrows, starlings, mynah birds, and people. Western equine encephalomyelitis virus has been recovered from this mite, but there is no evidence it transmits the virus.

For clinical findings and control, see above.

Turkey Chigger

The larvae of *Neoschongastia americana*, the turkey chigger, are parasitic on numerous birds. Across the southern USA, they are the major pest of turkeys ranged on heavy clay soils in the summer. The chiggers

feed in groups of as many as 100 mites per lesion for 8–15 days. Turkeys may have 25–30 lesions each. One lesion, 3 mm in diameter, may cause significant downgrading at market time. To prevent downgrading, turkeys must be protected for at least 4 wk before marketing.

Sprays or dusts of carbaryl, malathion, or chlorpyrifos on turkey ranges control chiggers. A preventive measure now used in many turkey-growing areas includes a shift from range to confinement rearing, or use of sheds to provide shade.

MOSQUITOES

Mosquitoes that feed on poultry blood usually belong to the genera *Culex*, *Aedes*, or *Psorophora*. Large numbers can decrease egg production or cause death. Mosquitoes transmit *Plasmodium gallinaceum* (chicken malaria), *Pharomacrus* (in turkeys), and other *Plasmodium* species causing avian malaria. They also transmit many viruses, including Eastern and Western equine encephalomyelitis,

St. Louis encephalitis, fowlpox, and West Nile viruses. West Nile virus is transmitted from infected birds to other birds primarily by mosquitoes, particularly *Culex* spp in the USA, and has been found in >200 species of birds in America, including chickens, turkeys, pigeons, budgerigars, cockatiels, ducks, finches, and birds of prey. (See also WEST NILE VIRUS INFECTION, p 2893.)

Removal of mosquito-breeding habitats by emptying water-filled containers, clearing pool and pond edges of emergent vegetation, draining swampy areas, and filling low areas that collect water are the best physical control measures. Insecticidal control involves chemicals such as malathion, propoxur, permethrin, chlorpyrifos, or temephos. Insect growth regulators such as methoprene and diflubenzuron are also effective. Microbial control of mosquito larvae uses *Bacillus thuringiensis israelensis* and, against *Culex* spp, *Bacillus sphaericus*. Screening to prevent mosquito entry, residual wall sprays, and fogging within poultry houses also aid in control.

GANGRENOUS DERMATITIS

(Necrotic dermatitis, Clostridial dermatitis, Gangrenous cellulitis, Gangrenous dermatomyositis, Gas edema disease)

Gangrenous dermatitis is a disease of turkeys and chickens caused by *Clostridium septicum*, *C. perfringens* type A, and *Staphylococcus aureus*, either singly or in combination. The condition is characterized by rapid onset of acute mortality. Birds succumbing to the infection have necrosis of the skin and subcutaneous tissue, usually involving the breast, abdomen, wing, or thigh.

Both clostridia and staphylococci are ubiquitous in the poultry house environment and in (intestine) or on (skin) the birds. The presence of these organisms, however, does not necessarily indicate a disease challenge. Other contributing factors are thought to play a major role in development of clinical disease within a flock. For example, gangrenous dermatitis often is believed to occur as a sequela of other diseases that produce immunosuppressive effects such as infectious bursal disease, chicken infectious anemia, reticuloendotheliosis, reovirus, and

inclusion body hepatitis. Environmental conditions that promote poor litter conditions may also predispose flocks to gangrenous dermatitis, especially when present in conjunction with challenges from immunosuppressive viruses. Failing to remove moribund or dead birds may increase incidence of the disease, because such birds serve as a reservoir for the causative agent(s). Management practices that lead to scratching, such as overcrowding, feed outages, meal time feeding, and bird migration in tunnel-ventilated houses may increase incidence of infection. Affected flocks tend to have repeat outbreaks if the environment is not treated. Incidence and severity of the disease depend on the bacterial strains involved in the infection, their ability to produce toxins, and the specific toxins produced.

Clinical Findings: The incubation period is relatively short (12–24 hr), with death occurring in well-fleshed birds. Other

Necrotic area of the skin with serosanguineous exudate due to clostridial infection in a chicken with gangrenous dermatitis. Courtesy of Dr. Jean Sander.

clinical findings are general in nature and include depression, incoordination, inappetence, leg weakness, ataxia, and high fever.

Lesions: Gross lesions consist of dark reddish purple to green, weepy areas of the skin. Affected areas usually include abdomen, breast, wings, or legs. Areas of affected dermis and subcutis are characterized by extensive blood-tinged edema, with or without gas (crepitus). Infection may extend into underlying musculature, which may be discolored and contain edema and gas. Lesions in turkeys may be seen around the tail head, with blisters and tissue edema present around the tail.

Diagnosis: Presumptive diagnosis may be assigned based on an acute increase in

mortality and characteristic gross lesions. Diagnostic confirmation is based on the presence of lesions and isolation of the causative agent(s) from affected tissue. Diagnosis of an underlying etiology is often necessary to fully understand the complexity of gangrenous dermatitis, because manifestation of the disease may be preceded by other immune-compromising infectious agents.

Treatment and Control: Total cleanout and disinfection of affected houses has reduced or eliminated gangrenous dermatitis infection on farms with historical problems. Salting of floors has also reduced bacterial challenge in subsequent flocks. Reducing excessive moisture and microbial levels in poultry house litter and minimizing trauma are useful adjuncts to other prevention and control measures. Where infection is secondary to predisposing viral infection, modification of vaccine programs directed at immunosuppressive agents may be used to control widespread gangrenous dermatitis.

Gangrenous dermatitis has historically been treated effectively with administration of many broad-spectrum and gram-positive antibiotics. Water acidifiers have been used in cases to reduce, but not eliminate, mortality where mortality rates are low or antibiotic efficacy has been poor.

Zoonotic Risk: The zoonotic potential and public health significance of gangrenous dermatitis is thought to be minimal, because nearly all affected birds succumb quickly to infection and do not survive to processing age.

DISORDERS OF THE SKELETAL SYSTEM

Production characteristics of modern poultry lines (eg, body weight in broiler chickens, egg production in laying hens) place high demands on the skeletal system, and inadequacies in nutrition or husbandry often result in skeletal diseases. Skeletal disorders may be primarily infectious or noninfectious; both may be seen concurrently within a flock. Skeletal disorders cause lameness from biomechanical dysfunction and in broiler chickens result in poor growth, culled birds, increased mortality (caused by starvation and dehydration), and carcass condemnation

and downgrading. Bone fractures in spent hens may be a welfare issue. Before postmortem examination, flocks should be assessed; live, lame birds should be examined, and general flock health and management assessed. Serum samples may be collected for viral and mycoplasmal serology and/or biochemistry (eg, serum calcium). Gross pathology alone is often insufficient, and histopathology is usually necessary to reach a diagnosis. Bone ash measurement, feed nutritional analysis, and bacteriology are useful complementary investigations.

NONINFECTIOUS SKELETAL DISORDERS IN BROILERS

Rotational (Torsional) and Angular (Valgus/Varus) Deformities: These deformities often are seen as distinct flock problems. The most common abnormalities are seen in the distal limb and involve lateral or medial deviation and/or external rotation. Valgus or varus deviation of the intertarsal joint is the most common deformation in broiler chickens. Males are more commonly affected. The pathogenesis of the leg deformation is not well defined. Deformity may be a consequence of rickets at a younger age (*see below*). Poor mineralization of the bone, as in rickets, increases the potential for deformation and therefore the incidence and severity of deformities. Bone deformities may also be due to chondrodystrophy secondary to nutritional deficiencies (eg, choline, biotin, pyridoxine, folic acid). In breeds predisposed to deformities, the incidence may be reduced by slowing the growth rate via feed restriction or lighting programs. Rotated tibia has been a major problem in turkeys and a minor problem in Leghorns and guinea fowl. Excessive external tibial rotation occurs during development, but the pathogenesis is not well understood. Genetic, nutritional, and management factors are thought to be involved. The lack of bone angulation differentiates rotated tibia from valgus and varus deformation.

Spondylopathies: Vertebral deformities and/or displacements (spondylopathies) such as lordosis and kyphosis are common in thoracic vertebrae, particularly at the level of the free thoracic vertebra. Spondylolisthesis ("kinky back") is a developmental disorder resulting in rotation of the free thoracic vertebra with ventral displacement of the anterior end and over-riding of the posterior end, causing spinal cord compression and posterior paralysis. Spondylolisthesis is the most common vertebral column deformity, but incidence is low in most broiler flocks. Growth rate and conformation influence this developmental disorder.

Dyschondroplasia: Dyschondroplastic lesions are masses of avascular cartilage extending from the growth plate into the metaphysis and are attributed to the failure of chondrocyte differentiation. This results in a focal thickening of the growth plate and is most commonly seen in the proximal

tibiotarsus (tibial dyschondroplasia). Dyschondroplasia can develop in other bones such as the proximal and distal femur and tarsometatarsus. The lesion in the proximal tibiotarsus can be associated with anterior bowing of the tibiotarsus and sometimes fractures distal to the plug of cartilage. Factors shown to influence the incidence and severity of dyschondroplasia include genetic selection, rapid growth, calcium:phosphorus ratio in feed, metabolic acidosis due to excess chloride in feed, acid/base imbalance, copper-deficient diet, *Fusarium* spp contamination of the feed, and exposure to dithiocarbamate fungicides and certain antibiotics such as salinomycin. The most common causes in modern broiler flocks may be marginal inadequacies in dietary calcium or a calcium:phosphorus imbalance. The disease is seen in broiler chickens, turkeys, and ducks.

Rickets: Rickets develops in growing birds due to deficiency of vitamin D, calcium, or phosphorus (*see p 2930 and p 2937*) or by calcium:phosphorus imbalance. Inadequate nutrition or intestinal disease with malabsorption can be the cause of the mineral or vitamin deficiency or imbalance. In rickets, abnormal endochondral ossification with failure of mineralization leads to defective bone formation, flexible long bones with subsequent bone deformities (eg, valgus, varus), and fractures. Lesions are most prominent at sites of rapid growth where cartilage contributes most significantly to skeletal growth (eg, long bones, ribs). Thick and pliable ribs and/or knobs at the costochondral junction (rachitic rosary) due to thickened and flared metaphyses are classic gross lesions. Beaks and claws can be soft and pliable. Hypertrophy and hyperplasia of the parathyroid glands are present. Subclinical rickets with only marginal thickening of the growth plates is fairly common and often associated with poor performance of broiler chickens. Bone pathology and bone ashing to estimate calcium and phosphorus content are useful diagnostic tools.

Degenerative Joint Disease: Degenerative joint disease is seen mainly in the coxofemoral, femorotibial, and intertarsal joints of broilers and male turkeys near market weight. Reluctance to move, abducted legs, and lameness can be observed. The pathogenesis is not well defined, but osteochondrosis or cartilage lesions and genetic factors may be involved.

NONINFECTIOUS SKELETAL DISORDERS IN BREEDERS

Osteopenia (Osteoporosis and Osteomalacia): Cage layer fatigue (see p 2897) describes a syndrome in which laying hens become paralyzed in their cages and have brittle bones. Layers 25–50 wk old are most severely affected. Osteopenia in cage layer fatigue is a consequence of osteoporosis, a deficiency in the quantity of normal fully mineralized structural bone, and osteomalacia, a reduction in bone density. The sternum is often deformed, and the ribs infolded at the junctions of the sternal and vertebral portions. Fractures occur in the long bones and vertebrae. Bone cortices are thin, and the medullary bone is osteomalacic. Parathyroid glands are hypertrophic and hyperplastic. This syndrome is due in part to a lack of exercise of hens held in cages and to selection for high egg production, but poor nutrition, with inadequate calcium, phosphorus, and/or vitamin D, exacerbates the condition. Although prevention of osteopenia in layers with nutritional management has not been successful, sources of calcium that enable the slow release of mineral, such as oyster shell, appear to give the best results to reduce development of osteopenia and improve eggshell quality.

Articular Gout: See p 2874.

INFECTIOUS SKELETAL DISORDERS

Coagulase-positive staphylococci (see also STAPHYLOCOCCOSIS, p 2867) are frequently responsible for bacterial infections in the bones and joints of broiler chickens.

Mycoplasma synoviae (see p 2843) may also play a role in infectious bone disorders.

In broilers, bacterial infections are most common in the proximal femur and proximal tibiotarsus in birds >22 days old. In the proximal femur, the condition is also referred to as femoral head necrosis, which is reported to be the most common cause of lameness in broiler chickens. The etiology appears to be vertically transmitted staphylococci, often in combination with infection by immunosuppressive viruses (eg, INFECTIOUS BURSAL DISEASE, see p 2837). Floor eggs have been shown to be common carriers of staphylococci, so their use should be avoided. A high standard of hatchery hygiene can reduce this risk. Formaldehyde fumigation within the hatchers is also likely to help. In addition, hatchery fluff samples (ie, hatching debris such as down

feather and egg shell remains) can be examined to monitor for contamination with staphylococci.

Staphylococcal infections in joints and tendons are also seen in breeders. Outbreaks are often due to bacterial infection subsequent to an existing tendinitis. A history of other diseases such as coccidiosis is often associated with an increase in staphylococcal infections in breeders. In some instances, reoviruses may also be isolated. (See also VIRAL ARTHRITIS, p 2886.) The virus is vertically transmitted. Vaccines against the condition have been developed.

Escherichia coli is often responsible for flock outbreaks of arthritis and osteomyelitis in broiler chickens and turkeys.

Osteomyelitis and arthritis are sequelae of septicemia, and these outbreaks may be associated with enteric or respiratory disease. Infection of bones, joints, and periarticular tissues with *E. coli*, *Staphylococcus aureus*, or *Shigella* is referred to as turkey osteomyelitis complex (TOC) or green-liver osteomyelitis complex. Green discoloration of the liver is often associated with TOC and is mostly observed at the processing plant but is rare in birds that died or are euthanized in the field.

Enterococcus cecorum is a commensal enteric bacterium that can cause epidemics of osteomyelitis, arthritis, and spondylitis in broilers and broiler breeders. Enterococcal spondylitis is a defined clinical syndrome

Osteomyelitis of the tibiotarsus in a 43-day-old broiler. Courtesy of Dr. H. J. Barnes.

with infection of the free thoracic and adjacent vertebrae, resulting in chronic osteomyelitis and spinal cord compression. Clinical signs of leg paresis often develop in broilers >35 days old.

Other sporadic causes of osteomyelitis and/or arthritis in poultry include *Pasteurella multocida*, *Ornithobacterium rhinotracheale*, *Trueperella* (*Arcanobacterium*) *pyogenes*, *Enterococcus* spp, *Streptococcus* spp, *Salmonella* spp, *Streptobacillus moniliformis*, and *Aspergillus* spp.

Osteomyelitis and arthritis are detected on gross examination by examination of articular surfaces and bone physes. Detection of subtle lesions requires histopathology. Affected joints are often swollen with fibrinous or caseous exudate. Bones have areas of lysis and/or replacement by caseous exudate, most often within the physal region.

Response to treatment with antibiotics currently approved for use in poultry is often poor for bacterial bone and joint infections. Antibiotics may be used to control the bacteremia contributing to new cases and to modify the bacterial flora within a flock. When individual birds are of high value, long-term antibiotic therapy may improve some less severe cases. Control requires minimizing sources of infection and stock susceptibility.

Viral Arthritis: See p 2886.

Osteopetrosis: Osteopetrosis in chickens is due to infection with specific strains of avian leukosis virus (see p 2851). Growth and differentiation of osteoblasts is altered by the virus, resulting in diaphyseal and/or metaphyseal, periosteal, and circumferential accumulation of woven and lamellar bone. Osteopetrosis is bilaterally symmetrical and involves the long bones, especially the tibiotarsus and tarsometatarsus. Birds 8–12 wk old are most commonly affected. Lymphoid leukosis often occurs in chickens with osteopetrosis. Avian osteopetrosis differs from mammalian osteopetrosis in which a defect in osteoclast function results in abnormal bone resorption and accumulation of primary spongiosa in the marrow cavity.

Amyloid Arthropathy: Extensive amyloid arthropathy is primarily caused by *Enterococcus faecalis* or *Mycoplasma synoviae*. Clinical cases are seen only occasionally and most frequently affect the hock joint. Brown layer chickens are particularly susceptible. Some cases have been attributed to contamination of a previously sterile vaccine diluent with *E. faecalis* during administration (eg, Marek's vaccine in day-old chicks). Joints may be enlarged by yellow-orange material in the articular space.

MYOPATHIES

EXERTIONAL MYOPATHY

Exertional myopathy results from overly strenuous muscular exercise and can be precipitated by preexisting conditions such as selenium deficiency. Inadequate energy metabolism and/or mechanical stresses occurring during contraction are thought to be the cause of myofiber degeneration. The lesions can be monophasic (resulting from a single event, eg, transport, capture, or restraint myopathy) or polyphasic (with repeated or ongoing events). Early gross lesions include muscle pallor with edema or bloodstained transudate. There is swelling, degeneration, necrosis, and mineralization of muscle fibers, with edema, hemorrhage, and infiltration of heterophils and macrophages. Deep pectoral myopathy and capture myopathy are the main examples of exertional myopathy in birds. Leg muscle

myopathy after transport of poultry can also occur and is associated with increased body size and weight, increased transport time to processing plant, cool ambient temperatures, and valgus leg deformities.

Deep Pectoral Myopathy

(Degenerative myopathy, Green muscle disease)

Deep pectoral myopathy is characterized by degeneration, necrosis, and fibrosis of the deep pectoral (supracoracoideus) muscle in heavy meat birds (chickens, turkeys), secondary to excessive muscle activity (exertional myopathy and compartment syndrome).

The function of the deep pectoral muscle is to elevate the wing. Although well-developed in modern meat birds, the muscle is little used. After episodes of prolonged wing

flapping (eg, handling, when a lame bird uses its wings to assist ambulation, or when a bird is placed on its back), deep pectoral muscle injury and swelling occurs. Because of the tight surrounding fascia, the swollen muscle cannot expand, which results in collapse of the blood vessels supplying the muscle. The decreased (or lack of) blood perfusion leads to ischemia, tissue hypoxia, and muscle necrosis (compartment syndrome). The lesion can be produced artificially by stimulating the deep pectoral muscle to contract and can be prevented by surgically opening the fascial sheath covering the muscle before exercise.

The myopathy may be unilateral or bilateral with the central $\frac{1}{3}$ – $\frac{2}{3}$ of the muscle most prominently affected. Early, the involved muscle is pale, swollen, and edematous. Later, it acquires a green coloration and becomes drier and sharply demarcated from adjacent, viable muscle. Eventually, the necrotic muscle becomes enclosed in a thick, fibrous capsule. The defect can be identified by a flattening or depression of the breast over affected muscles, by palpation, or by transillumination of carcasses at slaughter.

Flock prevalence is usually low, but prevalence as high as 25% has been reported, with few birds developing the disease before 24 wk of age. Deep pectoral myopathy occurs frequently in turkey breeder hens during artificial insemination. The disease is usually subclinical, and major loss is from downgrading or condemnation at processing. Deep pectoral myopathy is not easy to detect at processing when birds are marketed as whole carcasses.

Incidence can be decreased by careful handling of susceptible birds to prevent excessive wing flapping and, as a long-term method, by selective breeding because the condition has a genetic component. Supplementing rations with selenium, vitamin E, or methionine has not influenced incidence.

Capture Myopathy

Capture myopathy (exertional rhabdomyolysis) is mainly seen in zoo and wild birds and is rare in poultry. Long-legged wading birds are particularly susceptible. Capture myopathy results from exertion, struggle, or stress occurring during capture, handling, immobilization, or transport. Hyperthermia and metabolic acidosis due to anaerobic glycolysis are important factors. Pale skeletal muscle, especially muscle from the legs, or sometimes cardiac muscle, is seen grossly. However, no gross lesions are

present in peracute cases. Ischemic and myoglobinuric nephrosis may be present in birds that survive for a few days. Prognosis of symptomatic birds is usually poor, but treatment of single, valuable birds can be attempted and may be successful. Such treatment may consist of a combination of corticosteroids, vitamin E, selenium, parenteral fluids, and forced feeding in conjunction with physiotherapy. Prevention is best. Well-planned and executed capture and restraint that minimizes pursuit time, struggling, noise, and visual stimulation is key. Sedation or anesthesia can be useful.

Transport Myopathy of Turkeys

(Leg edema syndrome)

Heavy toms are primarily affected by transport myopathy, although it also develops in hens. Transport myopathy is associated with increased body size and weight, increased transport time to processing plants, cool ambient temperatures, and valgus leg deformities. The pathogenesis is unknown but presumed to be similar to that of exertional myopathy. Often, only one leg is affected. No evidence of external trauma is seen. Skin over edematous subcutaneous tissue is pale, feather follicles are less visible, and the skin slips easily over underlying muscle when moved. Occasionally, there is crepitation. Affected areas are dark when the edematous areas contain blood. Typically, when lesions are cut, the edematous subcutis is a few to several millimeters thick and is amber, occasionally green, or rarely red. Purulent exudate is absent, which distinguishes transport myopathy from cellulitis. If hemorrhage is present, the adductor muscles usually are torn. Removal of affected legs at processing results in carcass downgrading. Microscopically, acute multifocal muscle necrosis is found, primarily in the adductor muscles. Sometimes subacute or chronic lesions are seen, suggesting earlier episodes of myopathy. Serum CK increases sharply between farm and processing. This is now a rare disease because of programs designed to improve leg strength and conformation, as well as improved handling and transportation conditions.

MECHANICALLY INDUCED MYOPATHY

Avascular necrosis caused by pressure in heavy birds that are down because of lameness or leg deformity is seen occasionally and occurs most frequently in the breast

muscle. On gross examination, the tissue is firm and pale. Histologic examination reveals swelling, hyalinization, and necrosis of fibers with edema, heterophils, and macrophages at the periphery.

Rupture of the Gastrocnemius Tendon

Rupture of the gastrocnemius tendon is common in meat-type chickens, particularly roasters and breeders, and rare in turkeys. The rupture is due to application of excess weight to previously damaged tendons (most frequently by reoviral or staphylococcal tendinitis), or it can be spontaneous. The intra- and peritendinous fibroplasias that occur after infectious tendinitis make the tendon larger but weaker because of replacement of normal strong, dense tendon collagenous connective tissue with weaker, dense, irregular connective tissue. Synechiae between the tendon and its sheath may also develop, limiting the tendon's range of motion. Application of normal or excess weight to these previously damaged tendons results in partial or complete tearing or rupture. In noninfectious spontaneous tendon rupture, the cause of the rupture is uncertain but may be a combination of weaker tendons and heavier body weight in meat-type chickens. Rupture of the tendon of one leg puts stress on the other tendon, and bilateral rupture is frequent. Affected birds are lame or "down on their hocks" (creepers). Hemorrhage from the injury above the hock on the back of the leg is visible as red, blue, or green discoloration of the tissues, depending on the age of the lesion. No discoloration may be visible in chronic lesions. Tissue discoloration results in condemnation of the affected part at processing (red-leg, green-leg). The ruptured tendon can be palpated as a hard mass on the back of the leg above the hock. Broiler breeders >12 wk old are most commonly affected, and flock incidence may be as high as 20%.

Rupture of the Peroneus (Fibularis) Longus Muscle

The peroneus muscle originates on the proximal end of the tibiotarsus and patellar tissue, with attachments to other muscles in that area. In turkeys, the insertion appears to be in three places. A small band of tissue from the medial side of the muscle runs to the lateral tibial condyle. The main muscle tendon crosses the lateral side of the hock and joins other tendons that extend the hock and may affect foot and toe movement. The muscle is thin and wide, covering the anterior and lateral surface of the leg,

and is covered by a heavy aponeurosis in which the tendon is embedded. Rupture of the aponeurosis and muscle occurs as a 1–2 cm horizontal wound on the anterior and/or lateral surface of the muscle. It occurs above the middle of the tibiotarsus at the top of the ossifying tendon where the tendon attaches to the muscle. Rupture usually occurs at 10–14 wk, the age at which turkey leg tendons become ossified, reducing the elasticity of the tissue in that location.

Rupture of the peroneus longus muscle is an uncommon muscle lesion. It is most frequent in females and may affect as much as 5% of the flock. The separation of the muscle likely occurs slowly, caused by activity such as repeated springing, in turkeys that are becoming heavier and maturing earlier. Affected birds are not lame, but the resulting hemorrhage causes a red, blue, or green discoloration under the skin around and ventral to the rupture site (drumstick). This results in downgrading of the carcass at processing. The affected portion can be trimmed.

NUTRITIONAL MYOPATHY

Nutritional myopathy in chickens, turkeys, waterfowl, and ostriches is attributed to vitamin E/selenium deficiency. However, as in mammals, selenium deficiency is most often the main cause of the myopathy. Vitamin E deficiency, when accompanied by a sulfur amino acid deficiency, causes nutritional myopathy in chicks by ~4 wk of age. Lesions of vitamin E/selenium deficiency have been reported in skeletal (especially breast muscle), heart, and smooth muscle (gizzard and intestine) of ducks, turkeys, and chickens. Arsenic, zinc, copper, and other metals are antagonistic to selenium, and exposure to these other metals may precipitate outbreaks. Gross lesions, with pale foci or streaking, are similar to those of nutritional myopathies in mammals. Microscopic changes include focal or widespread myofiber swelling, edema, hyalinization, mineralization, degeneration, and lysis with infiltration of macrophages and heterophils. Hypercellularity from proliferation of satellite cells may be prominent if regeneration is occurring. Poultry feeds in many parts of the world contain added selenium at 0.1–0.4 ppm to prevent this myopathy.

TOXIC MYOPATHY

Ionophores are toxic at increased doses. Ionophore toxicity causes muscle damage

with incoordination, leg weakness, diarrhea, dyspnea, and reduced feed intake and weight. Stunting may also occur. Type I ("red muscle" or oxidative) fibers are most susceptible, and lesions are most prominent in the leg musculature. Lesions may also be found in heart and gizzard muscle. Adult birds (chickens, turkeys, ratites) and birds with no previous exposure are more sensitive to ionophore coccidiostats. Gross and histologic changes are similar to those of nutritional myopathy (see above). Ionophores promote movement of cations across the cell membrane, causing disruption of the ionic equilibrium, increased intracytoplasmic concentration of Ca^{2+} , and cell death. The toxic dose of ionophores is decreased if they are used in conjunction with tiamulin, erythromycin, or chloramphenicol. Salinomycin at the dose recommended for chickens (60 g/ton) is toxic for turkeys; doses >15 g/ton are toxic in turkeys. Monensin (100 g/ton) and lasalocid (100 g/ton) at the dose recommended for chickens are not toxic to turkeys.

Coffee senna (*Senna occidentalis*) toxicity can produce clinical signs and gross and histologic changes in muscles similar to those seen in ionophore toxicity.

INJECTION SITE INJURY

Injection of antibiotics and vaccines in any location can result in focal inflammatory myositis. Cellulitis and myositis in the neck region causing postural and/or neurologic signs can be seen in poultry after improper administration of vaccines. It is most commonly seen in broiler chicks. Affected birds may show ataxia, twisting of the neck, leg paralysis, and recumbency. Swelling of the subcutaneous and muscle tissue in the neck region at the injection site is seen grossly. Microscopically, a lympho-

cytic and/or granulomatous inflammatory infiltrate is present within the muscle and subcutis. The inflammatory infiltrate can extend to the epidural spaces. With oil-emulsion vaccines, empty spaces representing lipid droplets surrounded by a granulomatous inflammatory reaction can be seen.

MINIMAL MYOPATHY

A minimal myopathy is seen in otherwise normal meat-type poultry. Affected birds show no clinical signs, and their muscles are grossly normal, but microscopically there is mild myofiber degeneration and fat accumulation between myofibers. Focal or multifocal scattered myofibers are hyalinized and mineralized. More severe examples of this lesion contain individual myofiber necrosis, increased fat, and fibroplasia between fibers. No specific cause has been determined for these minimal changes, which have been observed by avian pathologists but are not described in the literature. Minimal myopathy is not an established name for this condition.

GENETIC MYOPATHY

Type II glycogen storage disease (acid maltase deficiency, Pompe disease) has been reported in Japanese quail. Symptoms start between 4 and 6 wk of age, and affected quail show progressive myopathy with reduced ability or inability to lift their wings, fly, or get back on their feet after being placed on their back (flip test). Glycogen deposition occurs in skeletal muscle, cardiac muscle, and smooth muscle, as well as in the brain and spinal cord. Both red and white muscle is affected, but lesions are more pronounced in the pectoralis superficialis (white muscle).

VIRAL ARTHRITIS

(Tenosynovitis, Reoviral arthritis)

Reovirus infections are ubiquitous in commercial poultry flocks. They are global in distribution, although the virulence of viruses appears to differ between regions. Most strains are nonpathogenic and appear to survive harmlessly in the intestine, whereas others have been associated with several disease conditions, including malabsorption and other enteric disorders,

hydropericardium, and occasionally respiratory disease. In many instances, the association of the reovirus with disease is uncertain. An exception to this is viral arthritis, or tenosynovitis, because it can be reproduced experimentally by infecting birds with reovirus alone.

Viral arthritis results in severe lameness in heavy broiler breeds of chickens and

occasionally in laying breeds. Although lameness in turkeys has sometimes been reported to be associated with avian reoviruses, experimental evidence in the past has been unable to confirm that turkeys are as susceptible to these viruses as chickens. However, recent field evidence from the USA indicates the presence of novel reoviruses causing arthritis and tendon rupture clinically identical to that in chickens. Reoviruses have been isolated from a range of other avian (including wild) species, and it is possible that cross-infection occurs, although ducks and geese have reoviruses that differ genetically from those of chickens.

Etiology and Pathogenesis: Viral arthritis is caused by avian reoviruses, which are RNA viruses related to but distinct from mammalian reoviruses. Strains differ in virulence, ranging from those causing arthritis and sometimes death to those that exist harmlessly in the gut. The mechanisms that determine whether a reovirus is pathogenic or harmless are poorly understood. Several antigenic types are known, and although some cross-protection occurs between types, it is rarely complete. Most infections are acquired by ingestion. After intestinal replication, the virus spreads via the bloodstream to all parts of the body. Pathogenic viruses localize in the hock joint, where they cause arthritis. Other organs, such as the liver, may be affected.

Transmission and Epidemiology:

Avian reoviruses can be egg transmitted, so infected breeder hens pass virus to chicks. Transmission is short-lived, and only a small nucleus of chicks carry virus. Infection is spread locally to hatchmates by the fecal-oral route. The virus is quite resistant to inactivation and can persist on farm materials for many days or weeks. Fomites are important.

Serious outbreaks of viral arthritis are followed by a decreased incidence in later hatch groups of birds from the same parent flock and may be related to decreased egg transmission and development of maternal immunity. Day-old chicks are more susceptible than older birds when exposed by natural means. The younger the chick when infected, the more likely it is that disease will develop.

Clinical Findings: Viral arthritis usually is seen in broilers 4–8 wk old as unilateral or bilateral swellings of the tendons of the shank and above the hock. It can also be found in much older chickens, usually at

peak of production or beyond, probably because of reactivation of persistent virus at sexual maturity. Affected birds walk with a stilted gait or prefer not to move. In the most severe form, rupture of the gastrocnemius tendon is common, although digital flexor tendons are sometimes affected and many cull birds are seen around the feeders and waterers. The most severely affected birds do not recover; less severely affected birds may recover in 4–6 wk. Infection is asymptomatic in many birds. Feed efficiency and rate of weight gain are decreased. Mortality is 2%–10% and morbidity 5%–50%.

Lesions: An acute, fulminating infection is occasionally seen in young chicks and embryos with cardiomegaly, hepatomegaly, and splenomegaly with necrotic foci. Edema around the tendons of the leg is marked, petechial hemorrhages develop in the synovial membranes above the hock, and fusion and calcification of the tendon bundles are common. Blood clots and hemorrhages are seen accompanying rupture of the gastrocnemius tendon. In the most severe cases, pitted erosions of the cartilage of the distal tibiotarsus are seen with flattening of the condyles. Histologically, the synovial cells are hypertrophied, hyperplastic, and infiltrated by lymphocytes and macrophages. The synovia contain lymphoid aggregates with heterophils and macrophages. In the heart, infiltration of heterophils or lymphocytes between myocardial fibers is a consistent finding.

Diagnosis: A presumptive diagnosis can be based on unilateral or bilateral swelling of the tendons of the shank and tendon bundle above the hock and on the inflammatory changes in the tendons and synovia described above. However, other causes of lameness such as *Mycoplasma synoviae* or *Escherichia coli* should be considered. Reovirus can be isolated from affected joints in primary chick embryo kidney, liver, or lung cell cultures, or via the yolk sac or chorionallantoic membrane of embryonated chicken eggs. In view of the widespread nature of reovirus infections without disease, isolation from the gut is not significant. In many laboratories, PCR is used for virus identification and is more rapid and sensitive than isolation. Avian reoviruses are now classified according to their sigma surface proteins, and the indications are that the novel USA turkey and European chicken viruses are different from the common ones associated with viral arthritis. The turkey isolates are genetically related to the turkey enteric reoviruses, but further molecular analysis

is awaited. In view of the ability of avian reoviruses to recombine, it is possible these new arthritogenic variants in both species have evolved by this means. ELISA is the serologic test of choice, and most birds are positive early in infection. Virus neutralization tests and challenge of immunized chickens can be used to identify the specific serotype. However, serologic results can be difficult to interpret in view of the ubiquity of reovirus infections. Culture procedures should be used to differentiate mycoplasmal and other bacterial infections.

Treatment and Control: There is no treatment. Live and killed vaccines are available. Maternal antibodies prevent early infection in chicks and minimize or

prevent egg transmission. In view of egg transmission and the greater susceptibility of baby chicks, the main objective of vaccination is to ensure good immunity in the parent flock. Vaccination programs should be directed to the serotype(s) present in local flocks. Adult birds are less susceptible to clinical disease if exposed by natural routes. Currently available commercial vaccines against viral arthritis are not effective against the newly encountered chicken viruses described in Europe or against those causing arthritis in turkeys.

Zoonotic Risk: There have been no reported zoonotic risks associated with avian reovirus infections.

AVIAN ENCEPHALOMYELITIS

(Epidemic tremor)

Avian encephalomyelitis (AE) is a viral disease of young chickens, turkeys, Japanese quail, pheasants, and pigeons. Turkeys are less susceptible to natural infection and generally develop a milder clinical disease than chickens. Ducklings and guinea fowl are susceptible to experimental infection. AE is characterized by neurologic signs that result from infection of the CNS with an RNA virus in the family Picornaviridae. Infection occurs via vertical and horizontal transmission. If a breeder flock becomes infected during egg production, the virus is vertically transmitted to the offspring and a major outbreak occurs. The disease often appears in a series of flocks hatched from the infected breeder flock. Field strains of the virus are enterotropic and multiply in the intestine. Infected birds shed the virus in their feces for a few days to a few weeks, which serves to spread the infection to hatchmates. There is no convincing evidence that the virus persists in infected birds. AE virus is resistant to environmental conditions and may remain infectious for long periods.

Clinical Findings: Vertically infected chicks commonly show clinical signs during the first week after hatching, although signs may be present in a few birds at hatching. Clinical signs appear later in hatchmates that are horizontally infected by the fecal-oral route. Vertical infection followed by horizontal infection causes a characteristic

biphasic mortality pattern. The main clinical signs are ataxia and leg weakness that varies from sitting on hocks to paresis that progresses to paralysis and recumbency. Fine tremors of the head and neck are evident in some birds and are characteristic of the disease. They are responsible for the common name, epidemic tremors. Tremors vary in frequency and severity and are best seen after birds are disturbed or excited. This can easily be done by placing the bird on its back and letting it right itself. Cupping the bird in one's hands often results in a buzzing feeling because of rapid, fine tremors. Severely affected birds lay on their side and exhibit intermittent fine tremors of the head, neck, and legs. Horizontally infected chicks usually show clinical signs at 2–4 wk of age; thus, clinical disease progresses through the flock for the first few weeks, and the episode is usually over by the time the flock is ~4 wk old. Morbidity and mortality rates vary and depend on the level of egg transmission and degree of immunity in the flock. In severe outbreaks, both morbidity and mortality may exceed 50%.

After 4 wk of age, chickens are resistant to disease but not infection. An exception occurs occasionally in older chickens after vaccination with egg-embryo-adapted commercial vaccines. Affected birds exhibit typical CNS signs like those seen in younger chicks.

In laying chickens, there is a sudden, 5%–10% drop in egg production, which

usually lasts for <2 wk, followed by a return to normal production. There is no deterioration in egg shell quality. Hatchability may drop as much as 5% during the decline in egg production due to late embryonic mortality. Infected eggs are laid during the period of viremia, which usually lasts 1–2 wk.

Lesions: No gross lesions are seen in the brain of infected birds. Gray to white foci may be visible on cut surfaces of the muscle of the gizzard. Weeks after infection, opacity of eye lenses (cataracts) may occur in a small percentage of chickens that survive the infection. Microscopic lesions in the CNS are found in the brain (cerebral peduncle, cerebellum, brain stem) and spinal cord and consist of degeneration and necrosis of neurons, perivascular lymphocytic cuffing, and gliosis with formation of glial nodules. In the cerebellum, there are areas of necrosis or loss of Purkinje cells and replacement by glial nodules that extend into the molecular layer of the gray matter. Neuronal lesions of central chromatolysis, shrinkage and increased basophilia, satellitosis, and neuronophagia are best found in neuron clusters (nuclei) in the brain stem, arbor vitae of the cerebellum, and lateral horn (gray matter) of the spinal cord. Central chromatolysis of neurons is characterized by rounding of the cell contour and displacement of Nissl granules to the periphery. Dorsal root ganglia have multifocal nodular collections of lymphocytes.

A common microscopic lesion outside the CNS is diffuse or nodular lymphocytic infiltrates in the gizzard muscle, muscular layer of the esophagus and proventriculus, myocardium, and pancreas. Except for cataracts, microscopic lesions generally are not found in infected adults unless they are

showing nervous signs, in which case they will have CNS lesions similar to those in young birds.

Diagnosis: Diagnosis is based on history, clinical signs, and characteristic histopathologic lesions in the brain and spinal cord. The diagnosis is best confirmed by isolation and identification of the virus. Tissues collected for virus isolation must include the brain and duodenum with the pancreas. Demonstration of AE virus antigen in the brain, spinal cord, and other tissues by immunofluorescent and immunohistochemical staining is a reliable method of diagnosis. The major differential diagnosis for neurologic signs in very young chicks is bacterial or mycotic encephalitis. Rickets and nutritional encephalomalacia are next in the list of differential diagnoses, although the clinical manifestations of these diseases differ from those in AE. In adults, serologic testing of acute and convalescent sera to demonstrate an increase in antibody titers helps establish a diagnosis.

Prevention: Immunization of breeder pullets at 10–15 wk of age with a commercial live vaccine prevents vertical transmission of the virus and provides progeny with maternal immunity. Vaccination of table-egg flocks is also advisable to prevent decreases in egg production. AE vaccine is usually combined with fowlpox vaccine and given by wing-web inoculation. Also available is a live fowlpox-vectored infectious laryngotracheitis and AE combination vaccine. Affected chicks and poults are ordinarily destroyed because they rarely recover.

AE virus does not cause disease in people or other mammals.

BOTULISM

(Limberneck, Western duck sickness)

Botulism is an intoxication that results from ingestion of preformed exotoxin of *Clostridium botulinum*. The disease occurs worldwide and has been identified in at least 117 species of wild birds representing 22 families. There is concern that endangered avian species may be at risk of extinction because of the disease. Mammalian species affected by the toxin include people, mink, ferrets, cattle, pigs,

dogs, horses, laboratory rodents, and various zoo animals. Intoxications are sporadic in poultry, but massive mortality has occurred in waterfowl. Ruminants fed poultry manure contaminated with *C. botulinum* spores have developed the disease.

Etiology: *C. botulinum* is a gram-positive, spore-forming, anaerobic bacterium. There are four genotypically distinct groups,

designated by the Roman numerals I to IV. All strains of *C botulinum* can produce neurotoxins that cause flaccid paralysis. Seven immunologically distinct toxins, designated by the letters A to G, are produced by different strains, which are classified into toxinotypes (A-G) according to the type of toxin produced.

Botulinum toxins are the most potent naturally occurring toxins. They are neurotoxins with an affinity for motor neurons. After absorption, the toxin binds irreversibly to the presynaptic membrane of cholinergic nerve terminals. It enters the cell and blocks release of acetylcholine across the neuromuscular junctions, resulting in flaccid paralysis. Death results from cardiac and respiratory failure. Outbreaks in poultry and waterfowl are predominantly caused by type C toxin. Type A toxin occasionally causes botulism in domestic chickens. Type E toxin has been the cause of botulism in fish-eating birds such as gulls.

C botulinum is ubiquitous, inhabiting soils and freshwater wetland (lakes, marshes) sediments. It is commonly found in the intestine of wild birds, but its presence in the intestine of healthy poultry is questionable. Spore germination and cell multiplication with toxin production require an anaerobic environment that must also provide the necessary substrates and conditions required for multiplication. For toxinotype C, optimal growth occurs between 25°C and 40°C, which may explain why most outbreaks of botulism in waterfowl occur during the summer and fall.

Epizootiology: Wetlands are home to numerous invertebrates that can accumulate high levels of botulinum toxin. Carcasses and organic matter provide suitable substrates for multiplication of *C botulinum* and toxin production. Invertebrates, especially fly larvae (maggots), feed on carcasses that have died from botulism and thus consume botulinum toxin. They are resistant to the toxins and concentrate them in their bodies. Outbreaks in waterfowl and other water birds result from consumption of toxin-laden invertebrates. Birds that die from botulism become infested with maggots, which perpetuates the outbreak in what is known as a "carcass-maggot cycle." Evidence suggests that botulism may also result from direct ingestion of decaying organic matter that contains toxin.

Outbreaks in commercial poultry are rare and generally tend to recur on the same

farm, often affecting the same houses or pens. The disease tends to be most severe in pen-reared pheasants with mortality up to 100%. Often, the source of the toxin in these outbreaks is difficult to find, leading to speculation that botulism in poultry is a "toxico-infection." Toxico-infection, also called "gut toxigenesis," results from proliferation of *C botulinum* in the intestine with subsequent production and absorption of the toxin. It is unclear what factors cause *C botulinum* to proliferate in the intestine and produce toxin. Studies have shown that healthy broilers do not harbor *C botulinum* type C in the ceca, and *C botulinum* was not recovered from the environment of poultry houses that did not have a history of botulism. These findings suggest that *C botulinum* is neither frequent nor widespread in broiler populations and that outbreaks result from infrequent and sporadic colonization of flocks with *C botulinum* introduced into a poultry house.

Clinical Findings: Clinical signs in poultry and wild birds are similar. Leg weakness and paresis that progress to flaccid paralysis of the legs, wings, neck, and eyelids are characteristic clinical signs. "Limberneck," the common name for botulism in birds, comes from the neck paralysis typically seen in affected birds. Signs in broiler chickens may also include ruffled or quivering feathers, feathers that are easily pulled out, labored breathing, and sometimes diarrhea with excess urates in loose droppings. Severely affected birds are in ventral recumbency on the floor with their eyes partially or completely closed and neck outstretched. They are unable to lift or hold their neck up and cannot raise their eyelids because of the flaccid paralysis that develops. Affected birds may have their legs extended behind them, because they are unable to pull them into a normal sitting position. Weakness is the earliest sign in waterfowl. Birds are initially reluctant to fly when approached and have weak wing-beats and difficulty taking flight. As the disease progresses, they lose their ability to fly and exhibit stumbling gaits and eventually paralysis. Birds in water can drown, because they cannot keep their heads above the water. The incubation period and time to onset of clinical signs is determined by the amount of toxin absorbed.

Lesions: *C botulinum* toxins do not cause lesions in affected birds, but maggots

or other invertebrates may be found in the crop. Carcasses are usually in good condition and do not show evidence of a chronic or debilitating disease.

Diagnosis: Preliminary diagnosis is based on clinical signs and absence of gross or microscopic lesions that can explain the neurologic signs. Definitive diagnosis requires demonstration of the toxin in serum from sick birds. Liver, crop contents, gizzard contents, and intestinal washes from moribund or very freshly dead birds may also be collected for toxin detection. Samples from dead birds are unreliable, because *C botulinum* toxin can result from postmortem multiplication of the organism and toxin production. It is preferred to collect serum from birds with clinical signs of varying severity. A bioassay test in mice (mouse-protection test) used to be the standard method to detect *C botulinum* toxins, but molecular tests based on ELISA are now preferred. PCR can be used on a variety of samples to detect the genes responsible for toxin production and differentiate the different toxinotypes. Because botulinum toxins are heat labile and can be destroyed at 80°C for ≥10 min, sera must be refrigerated or frozen as soon as possible after collection and shipped with ice packs to the testing laboratory.

Leg weakness or paralysis may be the only sign in mild intoxications, which must be differentiated from Marek's disease, drug and chemical toxicosis (especially ionophore toxicity), or appendicular skeletal problems. In waterfowl, botulism must be differentiated from chemical toxicosis, especially lead

poisoning, and acute, virulent infectious diseases (fowl cholera, duck viral enteritis, highly pathogenic avian influenza, etc).

Control and Prevention: Affected birds may recover without treatment. Antibiotics effective against clostridia may be useful if the disease is toxico-infectious. Collection and disposal of dead birds is critical to prevent and limit outbreaks, especially in pheasant and broiler chicken flocks. Fly control may reduce the risk of toxic maggots in the environment. Some, but not all, recurrent outbreaks in broiler flocks may be prevented by cleaning and disinfecting with products effective against spore-forming bacteria. Disinfection around poultry houses is suggested, because spores can be found outside of the houses and be reintroduced. In waterfowl outbreaks, ducks should be dispersed from affected areas and water levels stabilized. Elimination of large, shallow areas may prevent conditions favorable for decay of vegetation and die-off of invertebrates.

Active immunization with inactivated type C bacterin-toxoids has been successful in pheasant operations but is not cost-effective or feasible in commercial chickens and wild ducks. Treatment with type-specific antitoxin is effective but not practical.

Zoonotic Risk: The zoonotic potential of type C botulism is minimal. Botulism in people is caused mostly by toxin types A, B, and E. Furthermore, pathogenicity of toxin type C for people is questionable. However, botulism caused by type C toxin has been confirmed in several nonhuman primates.

VIRAL ENCEPHALITIDES

Encephalitis in poultry and farm-reared gamebirds may be caused by several different arboviruses. These include Eastern equine encephalitis (EEE) virus, Western equine encephalitis (WEE) virus, Highlands J (HJ) virus, Israel turkey meningoencephalitis virus, and West Nile virus (See also WEST NILE VIRUS INFECTION IN POULTRY, p 2893). The term "arbovirus," an abbreviation of arthropod-borne virus, is used to describe a virus that replicates in a hematophagous (bloodsucking) arthropod and is transmitted by bite to a vertebrate host.

Eastern Equine Encephalitis:

Eastern equine encephalitis (EEE) is most commonly a disease of horses (see p 1291); however, many outbreaks of EEE in farm-raised ringnecked pheasants and chukar partridges have been identified. EEE occurs only sporadically in other species of poultry (turkeys, ducks), game birds, and ratites (emus). EEE virus is found primarily in the eastern parts of North America, throughout Central America and the Caribbean, and in eastern parts of South America. In the USA, EEE has been identified in most states east of the

Mississippi River, as well as Louisiana and Texas; it is seen most often in Atlantic seaboard and Gulf Coast states. Reported isolations of the virus in Europe and Asia have not been confirmed.

EEE outbreaks generally occur in late summer and fall as a consequence of increasing numbers of mosquito vectors. *Culiseta melanura*, the principal mosquito vector, is likely responsible for transmission to poultry and game birds. Transmission to mammalian species most likely occurs by other mosquitoes such as *Aedes* and *Cooquillettia* spp, which feed on birds but also have a propensity to bite mammals. The virus has also been identified in a variety of other mosquitoes. Wild birds, primarily the smaller species of Passeriformes, are the principal vertebrate hosts of EEE virus. These birds rarely become ill but serve as maintenance and amplifying hosts for the virus in the transmission cycle.

Epornitics of EEE virus infection in pheasants are believed to be initiated by mosquito-borne infection of one or more birds in a flock, and subsequently spreading within the flock as a result of feather picking and cannibalism. In ratites, the virus may be transmitted by the fecal-oral route.

Clinical disease produced by EEE virus in poultry and game birds is usually attributed to CNS infection with or without visceral involvement. However, EEE also may produce visceral infections with little or no involvement of CNS tissues.

Pheasants develop incoordination, depression, leg paralysis, torticollis, and tremors. Mortality may be as high as 80%. Gross lesions are not observed; however, microscopic changes in the CNS consist of vasculitis, patchy necrosis, neuronal degeneration, and meningeal inflammation.

Chukar partridges exhibit clinical signs of depression, somnolence, and high mortality (30%–80%). Pale, focal areas generally are present on hearts of affected birds, and spleens are mottled and enlarged. Microscopic lesions consist of gliosis, satellitosis, perivascular lymphocytic infiltration in the brain, and myocardial necrosis with lymphocytic infiltration in the heart.

Turkeys with EEE virus infection may exhibit drowsiness, incoordination, progressive weakness, paralysis of legs and wings, and low mortality (<5%). In turkeys, EEE virus also has been identified as a cause of decreased egg production.

Ducklings infected with EEE virus develop a paralytic disease characterized by sudden onset, posterior paresis, and paralysis; mortality rates in affected flocks range from 2% to 60%. Microscopic lesions

consist of edema of spinal cord white matter, lymphocytic meningitis, and microgliosis.

Ratites exhibit depression, hemorrhagic diarrhea, emesis of bloodstained ingesta, and high mortality (as much as 80%). Hemorrhagic enteritis is the principal lesion seen on postmortem examination. Microscopic lesions include necrosis of hepatocytes and intestinal mucosa.

Western Equine Encephalitis: Western equine encephalitis (WEE) virus has many characteristics in common with EEE virus; however, it is rarely associated with disease in avian species. WEE virus was identified as the cause of encephalitis and high mortality in turkeys; affected turkeys exhibited somnolence, tremors, and leg paralysis. WEE virus also has been identified as a cause of decreased egg production in turkeys.

WEE is seen mainly in western parts of the USA and Canada, Central America, and South America. In the USA and Canada, it is transmitted principally by *Culiseta tarsalis*, a mosquito vector that is relatively common west of the Mississippi River.

Highlands J Virus: Highlands J (HJ) virus is a cause of encephalitis in chukar partridges. Chukars exhibit somnolence, ruffled feathers, and recumbency before death. HJ virus infection in this species is associated with high mortality. Microscopic lesions primarily consist of nonpurulent meningoencephalitis and focal myocardial necrosis. HJ virus can cause decreased egg production in turkeys. The virus has been identified only in eastern parts of the USA.

Israel Turkey Meningoencephalitis: Israel turkey meningoencephalitis has been reported only in turkeys. It generally occurs only in birds >10 wk old. While the specific vector has not been identified, the seasonal incidence and sporadic occurrence in flocks on the same farms strongly suggest that it is transmitted by insect vectors, most likely mosquitoes and *Culicoides*. Turkeys exhibit neurologic dysfunction characterized by progressive paresis and paralysis, with variable mortality. Morbidity and mortality rates average 15%–30% but may be as high as 80%. In turkey breeder hens, egg production drops severely. Gross lesions in affected turkeys include splenomegaly or atrophy of the spleen, catarrhal enteritis, and myocarditis. The principal microscopic lesions are nonpurulent meningoencephalitis characterized by submeningeal and perivascular lymphocytic infiltration and focal myocardial necrosis.

Diagnosis: Diagnosis of EEE, WEE, and HJ virus infection or Israel turkey meningoencephalitis may be confirmed by isolation and identification of the virus, detection of viral antigens in tissues by ELISA, detection of viral RNA in tissues using reverse transcriptase PCR procedures, and serologic testing. Virus can be isolated by inoculation of newborn mice, day-old chickens, embryonated chicken eggs, or a variety of cell cultures. Brain, spleen, liver, and serum are the preferred materials for diagnostic analyses.

Arbovirus infections must be distinguished from other causes of neurologic disease in poultry and game birds such as Newcastle disease virus (*see* p 2856,) avian encephalomyelitis virus (*see* p 2888), botulism (*see* p 2889), and listeriosis (*see* p 2839).

Prevention and Control: EEE, WEE, and HJ virus infection and Israel turkey meningoencephalitis are best prevented by measures aimed at reducing vector populations. Such measures include reduction of vector habitats by modifying the environment or by chemical spraying. If feasible, farms that raise susceptible avian species should be located away from swamps and other areas that provide habitat for vectors.

Formalin-inactivated EEE virus vaccines, prepared for use in horses, have been used to protect pheasants against EEE, although their efficacy has been questioned. One-tenth the equine dose of either an eastern or bivalent eastern and western vaccine is injected into the pectoral muscle, preferably at 5–6 wk of age or when birds are released from the brooder house.

Israel turkey meningoencephalitis also can be controlled by vaccination. A live attenuated vaccine has been prepared by serial passage of virus in Japanese quail kidney cells; this vaccine is highly efficacious and commercially available.

Zoonotic Risk: EEE and WEE viruses are zoonotic agents and potential causes of significant human disease. These viruses result in neurologic disease that may progress to paralysis, convulsions, coma, and death. The case fatality rate for EEE virus in people is 50%–75%, and survivors often have permanent neurologic sequelae. WEE virus is less severe, with a case-fatality rate of ~3%–7%; most infections are subclinical. Human infection usually is acquired by mosquito bite; laboratory and clinically acquired infections are rare. However, care should be taken to avoid contact or droplet exposure when handling suspect infected birds or performing necropsies.

WEST NILE VIRUS INFECTION IN POULTRY

See also EQUINE ARBOVIRAL ENCEPHALOMYELITIS, p 1291.

West Nile virus (WNV), a flavivirus related to the St. Louis encephalitis/Japanese encephalitis complex, was first isolated from the blood of a febrile Ugandan woman in 1937. The virus was first described as the cause of a West Nile fever epidemic in people in Israel in 1951; in a later outbreak, severe meningoencephalitis was seen in elderly patients. The role of mosquitoes in viral transmission was clearly delineated in a series of field studies in Egypt in the 1950s. Wild birds were identified as the reservoir of the virus around the same time. Cases of West Nile fever in horses were reported several years later. WNV was first associated with disease in domestic avian species in 1997, when flocks of young geese in Israel were affected with a neuroparalytic disease. In August 1999, the disease appeared for the first time in the Western hemisphere when wild and zoo birds, horses, and people

died in the northeast USA, notably in the New York City area.

Etiology and Epidemiology: WNV is considered to be endemic in many countries of Africa, Asia, southern Europe, and North America. Since 2001, serologic evidence of the spread of WNV into Latin America, the Caribbean, and South America has been reported. Epidemics appear in the human population at infrequent intervals in some of these countries, and there is evidence of viral transmission between Africa and Europe by migrating birds. Most outbreaks have occurred during the summer months and can continue until cold nights reduce mosquito vector activity, notably *Culex* spp.

Geese are the only known natural hosts of WNV among domestic avian species. Most of the flocks affected in the Israel outbreaks were 5–9 wk old, but goslings as young as 3 wk and as old as 11 wk were also affected.

Adult breeding flocks were clinically unaffected, but virus-neutralizing antibodies were found. Mortality of young Muscovy ducks but not young chickens or turkey poults was induced experimentally with a WNV isolate. While chickens are not killed by WNV, they do develop antibodies against the disease and have been used as sentinels to monitor WNV presence. Neither chickens nor turkeys develop high enough levels of viremia to infect mosquitoes or transmit the virus to other animals.

Transmission: The principal route of viral transmission is by the bite of a mosquito (primarily *Culex* spp.). In the USA during 1999 and 2000, most of the viral isolates were made from *C. pipiens* and *C. restuans*. WNV has been isolated, RNA detected, or antibodies found in 62 mosquito species in North America. In Africa and the Middle East, the usual vector is *C. univittatus*, and in Europe, *C. pipiens* and *C. modestus*. WNV has also been isolated from at least 10 tick species.

Clinical Findings: Affected geese show various degrees of neurologic involvement ranging from recumbency to leg and wing paralysis. Affected birds are either reluctant or unable to move when disturbed. Signs of incoordination are pronounced, and some birds flip over while attempting to stand. Naturally affected geese show torticollis and opisthotonos. Mortality rates of 20%–60% have been reported, probably due to horizontal spread of the virus.

Lesions: Pathologic changes include splenomegaly, hepatomegaly, and pallor of the myocardium and occasionally of the kidneys. The meningeal blood vessels are injected. Microscopic brain lesions consist of lymphocytic perivascular infiltration and neuronal degeneration. Small necrotic foci are present in the myocardium, but lymphocytic infiltration is minimal.

Diagnosis: The tissues of choice to isolate the virus from paralytic or dead birds are the brain, spleen, and kidneys. Homogenates are inoculated into the brain of newborn mice, into embryonated eggs by the yolk sac route, or into Vero and mosquito cell line cultures. Reverse transcriptase PCR with RNA extracted from either brain material or cell culture supernatant can also be performed. Gene expression assays/probes for rapid molecular diagnosis of field-collected mosquitoes and avian tissues are also available. Immunohistochemistry can be

used on formalin-fixed paraffin-embedded tissues, in particular brain and kidney, to visualize viral antigens in infected birds. Several forms of ELISA have also been developed for flaviviruses.

Neurologic signs in young geese must be distinguished from those caused by *Riemerella* infections, especially *R. anatipestifer*. Other bacteria include *Streptococcus gallolyticus*, and *Erysipelothrix*, *Listeria*, and *Salmonella* spp. Neurotropic viruses include Newcastle disease, which is rare in geese, and avian influenza. Isonophore intoxication can induce paralytic signs. *Aspergillus* also causes brain lesions and caseous nodules in the lungs.

Prevention and Control: Mosquito control is a mandatory component of any arboviral disease control program. Unfortunately, this is difficult to implement in a rural environment because of the distances that mosquitoes can fly or be carried by prevailing winds. Standing water and similar insect breeding sites in the vicinity of densely populated avian farms should be treated with larvicides. Poultry houses should be constructed to be insect free. Because many arboviral diseases are zoonoses, much can be achieved by cooperation with human disease surveillance agencies.

Control of WNV in geese is confined to vaccinating young flocks at risk, especially those raised during months when *Culex* spp. are most numerous. Because of confounding factors such as possible horizontal transmission of virus, all birds in the flock should be vaccinated. Because of the age-related susceptibility to the virus, goslings should be immunized as young as possible, preferably at 3 wk old. Currently, WNV vaccines are not available commercially in North America, although several types have been developed and widely used in domestic geese in Israel. Laboratory trials have been performed with a formaldehyde-inactivated suckling mouse brain-derived product. More than 75% of geese vaccinated with a single dose of vaccine at 3 wk of age were protected, and 94% protection was achieved with 2 doses given 2 wk apart. Inactivated vaccines prepared from chick embryos or Vero cells are not protective because of their low antigenic mass. Other vaccines either approved for use in geese or under study include poxvirus vector vaccines and subunit vaccines that use WNV components such as membrane protein or envelope protein.

ARTIFICIAL INSEMINATION

Artificial insemination (AI) is widely used to overcome low fertility in commercial turkeys, which results from unsuccessful mating as a consequence of large, heavily muscled birds being unable to physically complete the mating process. This is a serious and costly problem in the production of commercial turkey hatching eggs. In most commercial chicken production systems in the USA, it has not been necessary to implement AI programs because natural mating results in adequate fertility levels, but AI is routinely used in special breeding work and research. However, as managing commercial broiler breeders to maximize fertility becomes more challenging, the use of AI in commercial poultry operations outside the USA is becoming more common. Certainly, the use of AI in chickens, as in turkeys, can improve fertility; however, the cost of implementing AI on a large scale is often cost prohibitive.

Collecting semen from a chicken or turkey is done by stimulating the copulatory organ (the phallus) to protrude by massaging the abdomen and the back over the testes. This is followed quickly by pushing the tail forward with one hand and, at the same time, using the thumb and forefinger of the same hand to apply pressure in the area and to "milk" semen from the ducts of this organ. Semen flow response is quicker and easier to stimulate in chickens than in turkeys. The semen may be collected with an aspirator (turkeys) or in a small tube or any cup-like container. In turkeys, the volume averages ~0.35–0.5 mL, with a spermatozoon concentration of 6 to >8 billion/mL. In chickens, volume is 1–2 times that of turkeys, but the concentration is about one-half. Collected semen is usually pooled and diluted with an extender before use.

Chicken and turkey semen begins to lose fertilizing ability when stored >1 hr. Liquid cold (4°C) storage of turkey and chicken semen can be used to transport semen and maintain spermatozoal viability for ~6–12 hr. This short-term storage of semen is common in turkeys, while not as common in chickens. When using liquid cold storage for >1 hr, turkey semen must be diluted with a semen extender at least 1:1 and then agitated slowly (150 rpm) to facilitate oxygenation; chicken semen should be diluted and then cooled—agitation is not necessary. Chicken and turkey semen may

be frozen, but reduced fertility limits usage to special breeding projects. Under experimental conditions, fertility levels of 90% have been obtained in hens inseminated at 3-day intervals with 400–500 million frozen-thawed chicken spermatozoa.

Several commercial semen extenders are available and are routinely used, particularly for turkeys. Extenders enable more precise control over inseminating dose and facilitate filling of tubes. Results may be comparable to those using undiluted semen when product directions are followed. Dilution should result in an insemination dose containing ~300 million viable spermatozoa for turkeys. However, the number of spermatozoa inseminated will range from 150–300 million viable cells depending on the age of the turkey hens inseminated. In chickens, the number of diluted semen inseminated will range from ~100–200 million sperm cells per insemination. Producers usually determine the spermatozoa concentration and dilute the semen to obtain the appropriate sperm cell concentration for either the turkey or chicken.

For insemination, when holding the hen upright, pressure is applied to the abdomen around the vent, particularly on the left side. This causes the cloaca to evert and the oviduct to protrude, so that a syringe or plastic straw can be inserted ~1 in. (2.5 cm) into the oviduct and the appropriate amount of semen delivered. As the semen is expelled by the inseminator, pressure around the vent is released, which assists the hen in retaining sperm in the vagina or oviduct. When inseminating undiluted turkey semen, the high sperm cell concentration allows for 0.025 mL (~2 billion spermatozoa) to be inseminated at regular intervals of 7–10 days, yielding optimal fertility. In chickens, because of the lower spermatozoon concentration and shorter duration of fertility, 0.05 mL of undiluted pooled semen, at intervals of 7 days, is required. The hen's squatting behavior indicates receptivity and the time for the first insemination. For maximal fertility, inseminations may be started before the initial oviposition in turkeys, whereas this is not necessary in chickens. Fertility tends to decrease later in the season; therefore, it may be justified to inseminate more frequently or use more cells per insemination dose as hens age.

DISORDERS OF THE REPRODUCTIVE SYSTEM

CYSTIC RIGHT OVIDUCT

Fluid accumulation in the vestigial right oviduct is a common finding in hens. The abdominal cyst is filled with clear fluid and is attached to the right side of the cloacal wall. The cyst may vary in size from barely perceptible to 15–20 cm in diameter. An increased incidence has been seen in flocks after infectious bronchitis virus outbreaks. Oviductal cysts are a necropsy finding that rarely, if ever, affect flock performance.

DEFECTIVE OR ABNORMAL EGGS

Most “ridged,” “sunburst,” “slab-sided,” soft-shelled, or double-shelled eggs are the result of eggs colliding in the shell gland region of the oviduct when an ovum (yolk) is released too soon after the previous one. Necropsy examinations have demonstrated that two full-sized eggs can be found in the shell gland pouch. As the second egg comes in contact with the first, pressure is exerted, disrupting the pattern of mineralization. The first egg acquires a white band and chalky appearance, while the second egg is flattened on its contiguous surface (ie, slab-sided). Pimpled or rough eggs may have been retained too long in the shell gland. Blood spots result when a follicle vessel along the stigma ruptures as the ovum is being released. Meat spots occur when a piece of follicle membrane or residual albumen from the previous day is incorporated into the developing egg.

Many abnormalities appear to have no specific cause, but the incidence is much higher in hens subjected to stressful management conditions, rough handling, or vaccination during production. A significant increase in the number of soft-shelled eggs is also common as a result of viral diseases such as infectious bronchitis, egg drop syndrome, and Newcastle disease.

Small eggs with no yolk form around a nidus of material (residual albumen) in the magnum of the oviduct. Small eggs with reduced albumen and eggs with defective shells may be the result of damage to the epithelium of the magnum or shell gland.

Very rarely, foreign material that enters the oviduct through the vagina (eg, a roundworm) may be incorporated into an egg.

EGG-BOUND OR IMPACTED OVIDUCTS

A fully formed egg may lodge in the shell gland or vagina because the egg is too big (eg, double-yolked) or because of hypocalcemia, calcium tetany, or previous trauma (usually pecking) to the vent and/or vagina that obstructs oviposition. This condition may be more prevalent in young hens that are brought into production before body development is adequate or in hens that are overweight or obese. It occurs more often during spring and summer months because of overstimulation of birds by increasing light intensity and day length, which can be compounded by rapid increases in the amount of feed and/or excessive protein (lysine). This is a medical emergency in pet birds but is usually recognized only during necropsy in commercial poultry. When impaction occurs, eggs that continue to form create layers of albumen and yolk material, and the oviduct becomes very large. Some eggs are refluxed to the abdominal cavity (abdominal laying), and affected hens assume a penguin-like posture.

EGG PERITONITIS

(Egg yolk peritonitis)

Egg peritonitis is characterized by fibrin or albumen-like material with a cooked appearance among the abdominal viscera. It is a common cause of sporadic death in layers or breeder hens, but in some flocks may become the major cause of death before or after reaching peak production and give the appearance of a contagious disease. It is diagnosed at necropsy.

Peritonitis follows reverse movement of albumen and *Escherichia coli* bacteria from the oviduct into the abdomen. If the incidence is high, culture should be done to differentiate between *Pasteurella* (fowl cholera) or *Salmonella* infection. Antibiotic treatment of peritonitis caused by *E coli* infections is usually ineffective. Management of body weight and uniformity, reproductive development (ovary follicle growth and maturation), and drinking water sanitation are the best preventive strategies.

When hens have too many large ovarian follicles, a problem described as erratic

oviposition and defective egg syndrome (EODES) is seen in broiler breeders.

This condition is accompanied by a high incidence of double-yolked eggs, prolapses of the oviduct, internal ovulation, and/or internal laying that often results in egg peritonitis and mortality. EODES is prevented by avoiding light stimulation of underweight pullets too early and by following guidelines for body weight and uniformity, and lighting recommendations for each breeder strain. Overweight hens may also have a higher incidence of erratic ovulations and mortality associated with egg peritonitis.

FALSE LAYER

These hens ovulate normally, but the yolk is dropped into the abdominal cavity rather than being collected by the oviduct because of inflammation and resulting obstruction of the oviduct after infection with *Escherichia coli* or *Mycoplasma gallisepticum*. The yolk is absorbed from the abdominal cavity. The hen looks like a normal layer but does not produce eggs. Hypoplasia of the ovary and oviduct has been associated with infectious bronchitis virus infections (see p 2909) at an early age (1–2 wk). Atresia or even atrophy of the ovary are caused by severe stress, chronic infections, insufficient feed intake, inadequate feeder space, and feed refusal due to mycotoxins in the feed.

HYPOCALCEMIA, SUDDEN DEATH, OSTEOPOROSIS, OR CAGE LAYER FATIGUE

Pullets or hens with insufficient dietary calcium, phosphorus, or vitamin D₃ may die suddenly or be found paralyzed from hypocalcemia while shelling an egg. This may be associated with high production and withdrawal of calcium from bones for egg shell production, in which case the main lesion may be osteoporosis. At necropsy, there is an egg in the shell gland and the ova are active and fully developed. There are no other lesions, although medullary bone may be lacking. Paralyzed hens respond to calcium IV, and this response may be useful in diagnosis.

Osteoporosis is a major cause of death in high-production flocks. Hens with osteoporosis may show similar signs at necropsy, or the ova may be regressing with no egg in the oviduct. The femur is always fragile, and medullary bone is always absent in osteoporosis. These hens may also

respond to calcium IV if there are no fractures of the legs or vertebrae. The use of large particle size calcium (limestone, oyster shell) in the diet may be beneficial. High rates of mortality due to fractures are common in birds affected with osteoporosis. This situation is more common in broiler breeder hens in slatted houses due to the trauma caused by jumping on and off the slats. Ruptured egg follicles indicating trauma can be found during necropsy examination of these birds.

A condition known as hypocalcemia or calcium tetany (paralysis) has been seen in modern or high-yielding broiler breeder hens. Signs such as panting, spread wings, and prostration may be seen in the early morning hours preceding paralysis and death by asphyxia. Careful postmortem examination reveals a fully active ovary and the presence of a partially or fully formed egg in the shell gland in the absence of other lesions. This indicates that the hen used all available calcium from the bloodstream in an effort to complete the egg shell. The condition is common in flocks with poor body weight uniformity that are fed high-calcium diets in the weeks before the onset of lay and brought into production by drastic increases in day length and feed allocation. Hypocalcemia can be prevented by management practices that promote body weight uniformity and avoid excessive/premature allocation of high-calcium diets and light stimulation. Mortality can be reduced by the administration (“topping of the feed”) of 5 g of oyster shell per hen for 3 consecutive days, and addition of vitamin D₃ to the drinking water. This treatment should be suspended for 3 days and then repeated. Severe cases will require continual treatment for 2–3 wk (3 days of treatment followed by 3 days without). Feeding of recommended levels of calcium, using large-particle-size calcium, and providing adequate ventilation and cooling are helpful to prevent or reduce the incidence of this condition.

Mortality and the presence of an egg in the shell gland also can be caused by a condition referred to as sudden death syndrome, first reported in Australia. This is believed to be caused by marginal levels of potassium and phosphorus in the diet, resulting in cardiomyopathy.

INTERNAL LAYER

In these hens, partially or fully formed eggs are found in the abdominal cavity. Such eggs reach the cavity by reverse peristalsis of the oviduct. If they have no shell, they are often

misshapen because of partial or complete absorption of the contents. Frequently, only empty shell membranes are present. No control or treatment is known. This condition is related to erratic ovulation and defective egg syndrome (see p 2896).

INFERTILITY

Infertility caused by male management problems is common. Problems may be caused by an inadequate number of healthy males or because males have reduced sperm production resulting from chronic disease, inadequate feed intake, or starvation (harsh feed restriction). However, obese females may be less efficient in transporting sperm to the infundibulum, resulting in reduced fertilization of the ovum as it is released from the ovary. The male must be dominant to the females, or mating will not occur. Commercial turkey hens are inseminated artificially with semen collected from the toms and used the same day (see p 2895). Parthenogenesis is responsible for some infertility in turkeys. There are host sperm glands in the oviduct of females, and live sperm can be retained for 3–4 wk. Waterfowl have a rudimentary penis, and prolapse of the penis is occasionally reported in drakes. There is no treatment.

NEOPLASIA

The most frequent tumor of the reproductive system is adenocarcinoma of the oviduct. Neoplastic cells are shed from tumors in the oviduct into the abdominal cavity. They implant on the ovary, pancreas, and other viscera and produce multiple, hard, yellow nodules. They may block lymph return and result in ascites. The incidence increases with age, and this tumor may be a frequent cause of death after 2 yr. Affected hens are condemned at processing.

Leiomyoma of the broad ligament is an estrogen-induced hypertrophy of the smooth muscle of the broad ligament. It is benign and is an incidental finding at necropsy or processing.

A variety of ovarian and testicular tumors has been described. Marek's disease (see p 2849) is a common cause of tumors of the ovary.

OOPHORITIS AND OVARY REGRESSION

Regression of the ovary may result in leakage of free yolk into the abdomen (yolk peritonitis); this rarely causes death

except when yolk material migrates through the air sacs to the lung and causes foreign body pneumonia. Free yolk is seen in many cases of acute illness, injury, or forced molt. Regression of the ovary is frequently caused by low body weight, deliberate reduction of feed, overcrowding, or lack of feeder space. Infectious diseases such as Newcastle disease, fowl cholera, pullorum disease, and avian influenza are known to cause this condition. It can also result from severe stress, which is often accompanied by feather molt, emaciation, and dehydration.

PROLAPSE OF THE OVIDUCT

When an egg is laid, the vagina everts through the cloaca to deliver the egg. If there has been injury to the vagina, such as from a large or double-yolk egg, or if the hen is fat, the vagina may not retract immediately, leaving it exposed for a short time. This may result in cannibalism (see p 2873). When the protruding organ is pecked by other hens, the complete oviduct and parts of the adjacent intestinal tract may be pulled from the abdominal cavity ("peckout"). Bleeding from the vent is observed as a result of pecking. Alternatively, the vagina swells, cannot retract, and remains prolapsed ("blow-out"). The hen dies from shock. Prolapse has been associated with excessive/premature photostimulation, poor body weight uniformity, early laying (inadequate body size), large eggs, double-yolked eggs, and obesity. Cannibalism may be prevented by beak trimming, managing light intensity, maintaining appropriate stocking density, and avoiding nutritional deficiencies.

SALPINGITIS

Salpingitis is an inflammation of the oviduct, which may contain liquid or caseous exudate. In young pullets, it is often due to *Mycoplasma gallisepticum*, *Escherichia coli*, *Salmonella* spp, or *Pasteurella multocida* (fowl cholera) infection and can result in reduced egg production. It is a frequent lesion in female broilers and ducks at processing. On gross examination, salpingitis may be difficult to differentiate from impacted oviduct in adults. As the oviduct becomes nonfunctional, the ovaries are usually atrophied. Unless associated with an infectious problem, this condition tends to be found sporadically during necropsy of cull hens.

SEX REVERSAL

If the normal left ovary of a hen is destroyed by infection, the vestigial right organ may develop as a testicle and the hen may develop male characteristics.

Neoplasia in the adrenal glands or ovary that result in the production of testosterone could also cause the development of male secondary sexual characteristics (comb and wattles) in affected females.

EGG DROP SYNDROME '76

Egg drop syndrome '76 (EDS '76) is an adenovirus-induced disease characterized by the production of pale, soft-shelled, and shell-less eggs by apparently healthy laying hens. The disease in laying hens has commonly been called "egg drop syndrome," but the full name (egg drop syndrome '76 [EDS '76]) should be used to distinguish it from the recently recognized flaviviral disease of ducks, which has been called "egg drop syndrome in ducks," and "duck egg drop syndrome," creating potential for confusion.

Etiology: EDS '76 is caused by a double-stranded DNA virus, duck adenovirus 1 (also known as EDSV), which belongs to the genus *Adenovirus*. The virus commonly infects both wild and domestic ducks and geese, but evidence of infection has also been found in coots, grebes, herring gulls, owls, storks, swans, and quail. The adenovirus group antigen cannot be demonstrated by conventional means, and EDSV differs from other avian adenoviruses by strongly agglutinating avian RBCs, a fact that allows use of a hemagglutination-inhibition test for detection of antibodies to the virus. The virus grows to high titers in embryonated duck and goose eggs and in cell cultures of duck or goose origin. It replicates well in chick-embryo liver cells, less well in chick kidney cells, and comparatively poorly in chick-embryo fibroblasts. It does not grow in embryonated chicken eggs or in mammalian cells. The virus is resistant to pH range 3–10 and to heating for 3 hr at 56°C (132.8°F). Infectivity is lost after treatment with 0.5% formaldehyde or 0.5% glutaraldehyde.

Only one serotype of EDSV has been recognized to date.

Epidemiology and Pathogenesis: The natural hosts for EDSV are ducks and geese. It is thought that the virus was introduced to chickens through a vaccine that had been

grown in contaminated duck-embryo fibroblasts. The virus became established in chickens, causing substantial problems with egg shell quality and loss of eggs. All ages and breeds of chickens are susceptible to infection. Disease tends to be most severe in heavy broiler-breeders and hens producing brown eggs. Japanese quail (*Coturnix coturnix japonica*) also develop disease. There are rare reports that the egg drop syndrome virus (EDSV) has caused either a drop in egg production or respiratory tract disease in other species, eg, turkeys, ducks, geese, and quail.

Three patterns of disease are recognized in chickens: 1) Classical EDS '76 occurs when primary breeding stock are infected and the virus is transmitted vertically through the egg. The virus often remains latent until the progeny chick reaches sexual maturity, at which time the virus is excreted in the eggs and droppings, infecting susceptible contacts. 2) Endemic EDS is the result of horizontal infection of the flock during lay. It is usually seen in commercial egg layers. Contaminated egg collection trays are one of the main vehicles of horizontal transmission between flocks, and outbreaks are often associated with a common egg-packing station. 3) Sporadic EDS '76 has been recognized occasionally in flocks. This is due either to direct contact with domestic ducks or geese or, more often, to use of a water supply contaminated with wildfowl droppings. Although infection by this route is uncommon, there is always a risk that these introductions of the virus could form a starting point for endemic disease.

The main method of horizontal spread is through contaminated eggs or equipment such as trays, crates, trucks, or personnel. Droppings are also infective. The virus can be transmitted by bleeding or vaccination needles. Insect transmission may be possible but has not been proved.

After horizontal infection, the virus grows to low titers in the nasal mucosa. This is followed by viremia, virus replication in lymphoid tissue, and then massive replication for ~5 days in the pouch shell gland. Changes in the egg shell coincide with viral replication in the shell gland. Both the exterior and interior of eggs produced between 8 and ~18 days after infection contain virus. Exudate and secretions from the oviduct are rich in virus and pass into the droppings, which may become mildly to moderately watery for 2–3 days. Unlike other fowl adenoviruses, there is little, if any, virus growth in the epithelial cells of the intestine. Interestingly, the massive viral replication in the pouch shell gland occurs after seroconversion, a fact that is useful diagnostically.

Chicks hatched from infected eggs may excrete virus and develop antibody. More often, the virus remains latent, and antibody does not develop until the bird starts to lay, at which time the virus reactivates and grows in the oviduct, repeating the cycle.

Clinical Findings: In flocks without antibody, the first sign of the disease is the production of pale-shelled eggs, quickly followed by production of soft-shelled and shell-less eggs. Internal quality of eggs is unaffected in experimentally induced disease. Transient dullness may be seen in the days before the shell changes are noticed. The thin-shelled and shell-less eggs are fragile, and the birds tend to eat them; these eggs also may get trampled into litter and may be overlooked unless a careful examination is made. Although it has been shown experimentally that eggs usually continue to be produced at a normal rate

(so the disease name may be a misnomer), the number of useable eggs produced falls by 10%–40%. Egg production by the flock usually returns to normal. In flocks in which there has been some spread of virus and some of the birds have antibody (usually 10%–20%), the condition is seen as a failure to achieve predicted production targets; careful examination shows that these flocks experience a series of small group episodes of infection and disease. Birds with antibody slow the spread of virus.

There is no effect on fertility or hatchability of those eggs with a shell quality that is satisfactory for setting.

Diagnosis: Production of pale, thin-shelled and shell-less eggs by a flock that appears otherwise healthy should raise strong suspicion of EDS '76. Transient mild depression and/or mild watery droppings may be noted. Ridged eggs and poor internal quality are not features of EDS '76. Poor egg shell quality at peak production in healthy hens should also raise strong suspicion of classical EDS '76. With endemic or sporadic EDS '76, disease can develop in laying hens of any age. In cage units, spread can be slow, and the signs may be overlooked or perceived as a small depression (2%–4%) of egg yield.

Clinically, EDS '76 can be distinguished from Newcastle disease (*see* p 2856) and influenza virus infections (*see* p 2902) by the absence of illness, and from infectious bronchitis (*see* p 2909) by the absence of respiratory signs, the absence of ridged and malformed eggs, and the absence of poor internal egg quality. Confirmatory laboratory testing is needed for definitive diagnosis. Searching for evidence of seroconversion is the easiest diagnostic approach for nonvaccinated flocks. When selecting birds for diagnosis, especially in cage units, it is important to target hens that have produced affected eggs, because if the problem is due to EDSV infection, these hens will already have seroconverted. A hemagglutination-inhibition test using fowl RBCs, and ELISA, are the serologic tests of choice. In addition, the serum neutralization test can be used for confirmation. The double immunodiffusion test also has been used. PCR-based tests and antigen capture ELISA tests have been used to detect EDSV DNA and antigen, respectively. Again, appropriate selection of the hens to be examined is very important. EDSV can be isolated by inoculating embryonated duck or goose eggs or duck- or chick-embryo liver cell cultures. It is important to select recently infected birds for testing, but these

Eggs produced by hens in a flock with EDS '76. One normal egg is present (center, back row). Affected eggs include pale and thin-shelled eggs and shell-less eggs. The contents of the egg at the bottom right have been lost, leaving a thick, collapsed shell membrane. Courtesy of Dr. Joan Smyth.

can be difficult to identify, especially if the birds are on litter. An easier method is to feed affected eggs to antibody-free hens. These hens can then be tested for seroconversion after the first abnormal eggs are produced, or tested for evidence of EDSV DNA or antigen by PCR or antigen capture ELISA, respectively, or virus isolation can be attempted from the pouch shell gland of these hens.

Control: There is no treatment for EDS '76. The classic form has been eradicated from primary breeders. Use of dedicated equipment and egg trays for each farm, and/or washing and disinfecting plastic egg trays before use, can help to control the endemic form. The sporadic form can be

prevented by separating chickens from other birds, especially waterfowl. General sanitary precautions are indicated, and potentially contaminated water should be chlorinated before use.

Inactivated vaccines with oil adjuvant are available and, if properly administered, successfully prevent the disease. They reduce but do not prevent virus shedding. These vaccines are given during the growing period, usually at 14–18 wk of age, and can be combined with other vaccines, such as those for Newcastle disease. Sentinel chickens may be placed along with vaccinated chickens and periodically checked for antibodies, which would allow detection of the presence of virus in the flock.

AIR SAC MITE

Cytodites nudus is a small cosmopolitan mite occasionally noticed as white spots on the bronchi, lungs, air sacs, and abdominal organs of chickens, turkeys, pheasants, pigeons, canaries, and mallards. (See also p 1906.) These mites are readily transmissible between birds through coughing. They are rarely found in commercial industries. The 14- to 21-day life cycle involves a larval

and two nymphal stages. Infestation densities vary, and clinical signs range from none to weakness, weight loss, pneumonia, peritonitis, pulmonary edema, and death. Recommended treatments include ivermectin, a nearby dichlorvos pest strip (placed out of reach of the birds), topical moxidectin, or a pyrethrin/piperonyl butoxide spray.

ASPERGILLOSIS

(Brooder pneumonia, Mycotic pneumonia, Pneumomycosis)

Aspergillosis is a disease, usually of the respiratory system, of chickens, turkeys, and less frequently ducklings, pigeons, canaries, geese, and many other wild and pet birds. In chickens and turkeys, the disease may be endemic on some farms; in wild birds, it appears to be sporadic, frequently affecting only an individual bird. Severe outbreaks usually occur in birds 7–40 days old. (See also ASPERGILLOSIS in mammals, p 633, and in PET BIRDS, p 1899.)

Etiology and Epidemiology: *Aspergillus fumigatus* is a common cause of the disease. However, several other *Aspergillus* spp may be incriminated.

High mortality rates are seen in chicks and poults that inhale large numbers of

spores during hatching in contaminated incubators or when placed on mold-bearing litter. In older birds, infection is caused primarily by inhalation of spore-laden dust from contaminated litter or feed or dusty range areas. Morbidity can be underestimated in finishing flocks until slaughter inspection reveals pulmonary lesions.

Clinical Findings and Lesions: Dyspnea, hyperpnea, somnolence and other signs of nervous system involvement, inappetence, emaciation, and increased thirst may be seen. In chicks or poults up to 6 wk old, the lungs are most frequently involved. Airsacculitis is a cause of postmortem condemnation in young mature turkeys intended for food supply. Pulmonary lesions are characterized

by white to yellow plaques and nodules a few mm to several cm in diameter; occasionally, mycelial masses may be seen within the air passages on gross examination. The plaques and nodules also may be found in the syrinx, air sacs, liver, intestines, and occasionally the brain. The encephalitic form is most common in turkeys. An ocular form is seen in chickens and turkeys as mycotic keratitis, in which large plaques may be expressed from the medial canthus.

Diagnosis: The fungus can be demonstrated by culture or by microscopic examination of fresh preparations. One of the plaques is teased apart and placed on a suitable medium, usually resulting in a pure culture of the organism. Histopathologic examination using a special fungus stain reveals granulomas containing mycelia.

Differential diagnoses include infectious bronchitis, Newcastle disease, infectious laryngotracheitis, mycobacteriosis, colibacillosis, other mycoses (eg, ochro-

conosis, zygomycosis), and nutritional encephalomalacia.

Treatment and Control: Treatment of affected birds is generally ineffective. Spontaneous recovery from pulmonary aspergillosis can occur if reexposure to the mold is prevented. Strict adherence to sanitation procedures in the hatchery minimizes early outbreaks. Grossly contaminated or cracked eggs should not be set for incubation, because they enable bacterial and fungal growth and may explode and disseminate spores throughout the hatching machine. Contaminated hatcheries should be thoroughly cleaned and fumigated with enilconazole or formaldehyde. Avoiding moldy litter or ranges serves to prevent outbreaks in older birds. Cleaned pens should be sprayed or fumigated with enilconazole following label directions, and all equipment should be cleaned and disinfected.

AVIAN INFLUENZA

Avian influenza (AI) viruses infect domestic poultry as well as pet, zoo, and wild birds. In domestic poultry, AI viruses are typically of low pathogenicity (LP), causing subclinical infections, respiratory disease, or drops in egg production. However, a few AI viruses cause severe systemic infections with high mortality. This highly pathogenic (HP) form of the disease has historically been called fowl plague. In most wild birds, AI viral infections are subclinical except for the recent H5N1 HP AI viruses of Eurasian lineage.

Etiology: AI viruses are type A orthomyxoviruses characterized by antigenically homologous nucleoprotein and matrix internal proteins, which are identified by serology in agar gel immunodiffusion (AGID) tests. AI viruses are further divided into 16 hemagglutinin (H1-16) and 9 neuraminidase (N1-9) subtypes based on hemagglutinin inhibition and neuraminidase inhibition tests, respectively. Most AI viruses (H1-16 subtypes) are of low pathogenicity, but some of the H5 and H7 AI viruses are highly pathogenic for chickens, turkeys, and related gallinaceous domestic poultry.

Epidemiology and Transmission: LP AI viruses are distributed worldwide and are recovered frequently from clinically normal shorebirds and migrating waterfowl. Occasionally, LP viruses are recovered from imported pet birds and ratites. The viruses may be present in village or backyard flocks and other birds sold through live-poultry markets, but most commercially raised poultry in developed countries are free of AI viruses. The HP viruses arise from mutation of some H5 and H7 LP viruses and cause devastating epidemics. Stamping-out programs are used to quickly eliminate the HP viruses in developed countries, but some developing countries may use vaccines to control HP viruses.

The incubation period is highly variable and ranges from a few days in individual birds to 2 wk in the flock. Transmission between individual birds is by ingestion or inhalation. Naturally and experimentally, cats and dogs have been infected with one strain of H5N1 Eurasian HP AI virus. Experimental infections occurred after respiratory exposure, ingestion of infected chickens, or contact exposure, but cats were more susceptible than dogs. Potentially, domestic pets could serve as a transmission vector between farms, but the ability of other AI

viruses, including other H5N1 strains, to infect pets is unknown. Other mammals that have been experimentally infected include pigs, ferrets, rats, rabbits, guinea pigs, mice, mink, and nonhuman primates. Transmission between farms is the result of breaches in biosecurity practices, principally by movement of infected poultry or contaminated feces and respiratory secretions on fomites such as equipment or clothing. Airborne dissemination between farms may be important over limited distances. Limited spread by wild birds of the Eurasian H5N1 HP AI virus has been suggested but is not typical of other HP AI viruses. Other HP AI and all LP AI have minimal potential to infect dogs and cats.

Clinical Findings and Lesions: Clinical signs, severity of disease, and mortality rates vary depending on AI virus strain and host species.

Low Pathogenicity Avian Influenza Viruses: LP AI viruses typically produce respiratory signs such as sneezing, coughing, ocular and nasal discharge, and swollen infraorbital sinuses in poultry. Sinusitis is common in domestic ducks, quail, and turkeys. Lesions in the respiratory tract typically include congestion and inflammation of the trachea and lungs. In layers and breeders, there may be decreased egg production or fertility, ova rupture (evident as yolk in the abdominal cavity) or involution, or mucosal edema and inflammatory exudates in the lumen of the oviduct. A few layer and breeder chickens may have acute renal failure and visceral urate deposition (visceral gout). The morbidity and mortality is usually low unless accompanied by secondary bacterial or viral infections or aggravated by environmental stressors. Sporadic infections by any subtype of LP AI viruses can occur, but H9N2 LP AI is common in poultry in Asia, the Middle East, and North Africa.

High Pathogenicity Avian Influenza Viruses: Even in the absence of secondary pathogens, HP AI viruses cause severe, systemic disease with high mortality in chickens, turkeys, and other gallinaceous poultry; mortality can be as high as 100% in a few days. In peracute cases, clinical signs or gross lesions may be lacking before death. However, in acute cases, lesions may include cyanosis and edema of the head, comb, wattle, and snood (turkey); edema and red discoloration of the shanks and feet due to subcutaneous ecchymotic hemorrhages; petechial hemorrhages on visceral organs and in muscles; and blood-tinged

oral and nasal discharges. In severely affected birds, greenish diarrhea is common. Birds that survive the peracute infection may develop CNS involvement evident as torticollis, opisthotonos, incoordination, paralysis, and drooping wings. The location and severity of microscopic lesions are highly variable and may consist of edema, hemorrhage, and necrosis in parenchymal cells of multiple visceral organs, skin, and CNS.

Diagnosis: LP and HP AI viruses can be readily isolated from oropharyngeal and cloacal swabs, and HP AI viruses from many internal organs. AI viruses grow well in the allantoic sac of 9- to 11-day-old embryonating chicken eggs, and they agglutinate RBCs. The hemagglutination is not inhibited by Newcastle disease or other paramyxoviral antiserum. AI viruses are identified by demonstrating the presence of 1) influenza A matrix or nucleoprotein antigens using AGID or other suitable immunoassays, or 2) viral RNA using an influenza A-specific reverse transcriptase-PCR test.

LP AI must be differentiated from other respiratory diseases or causes of decreased egg production, including 1) acute to subacute viral diseases such as infectious bronchitis, infectious laryngotracheitis, low virulent Newcastle disease, and infections by other paramyxoviruses; 2) bacterial diseases such as mycoplasmosis, infectious coryza, ornithobacteriosis, turkey coryza, and the respiratory form of fowl cholera; and 3) fungal diseases such as aspergillosis. HP AI must be differentiated from other causes of high mortality such as virulent Newcastle disease, peracute septicemic fowl cholera, heat exhaustion, and severe water deprivation.

Prevention and Treatment: Vaccines can prevent clinical signs and death. Further-

Hemorrhagic skin visible on the feet of a chicken with avian influenza. Courtesy of Dr. David E. Swayne.

more, viral replication and shedding from the respiratory and GI tracts may be reduced in vaccinated birds. Specific protection is achieved through autogenous virus vaccines or from vaccines prepared from AI virus of the same hemagglutinin subtype. Antibodies to the homologous viral neuraminidase antigens may provide partial protection. Currently, only inactivated whole AI virus, recombinant fowlpox-AI-H5, and recombinant herpesvirus-turkey-AI-H5 (rHVT-AI-H5) vaccines are licensed in the USA. The use of any licensed AI vaccine requires approval of the State Veterinarian. In addition, use of H5 and H7 AI vaccines in the USA requires USDA approval. Treating LP-affected flocks with broad-spectrum antibiotics to control secondary pathogens and increasing house temperatures may reduce morbidity and mortality. Treatment with antiviral compounds is not approved or recommended. Suspected outbreaks should be reported to appropriate regulatory authorities.

Zoonotic Risk: AI viruses exhibit host adaptation to birds. Human infections have

occurred, usually as isolated, rare, individual cases. Most human cases have originated from infection with Eurasian H5N1 HP AI virus and, most recently, Chinese H7N9 LP AI virus. The total accumulated human cases of H5N1 HP AI virus in Asia and Africa from 2003–2013 is 648, of which 384 were fatal. The primary risk factor for human infection has been direct contact with live or dead infected poultry, but a few cases have resulted from consumption of uncooked poultry products, defeathering of infected wild swans, or close contact with human cases. Respiratory infection has been the most frequent presentation of human H5N1 cases. For H7N9 LP AI, total accumulated human cases in China for 2013 is 137, of which 45 were fatal. Most cases had exposure risk to live-poultry markets. Conjunctivitis was the most frequent symptom in human cases of H7N7 HP AI virus infection in the Netherlands during 2003, with 89 confirmed cases and 1 fatality. Other HP AI viruses and all LP AI viruses have produced very rare or no human infections.

AVIAN METAPNEUMOVIRUS

(Turkey rhinotracheitis, Avian pneumovirus, Swollen head syndrome)

Avian metapneumovirus (aMPV) causes turkey rhinotracheitis, an acute respiratory tract infection of turkeys. It is also associated with swollen head syndrome in broilers and broiler breeders, as well as egg production losses in layers. The virus was first detected in turkeys in South Africa in the late 1970s and has spread to all the major poultry-producing areas in the world except for Australia. aMPV has been detected not only in chickens and turkeys but also in pheasants, Muscovy ducks, and guinea fowl. Geese, most other duck species, and possibly pigeons are suggested to be refractory to disease. Epidemiologic studies provide evidence for the circulation of aMPV in wild birds, especially water-associated species. Some outbreaks have been attributed to vaccine-derived viruses, which may persist for several months in the environment. Infection with aMPV is often complicated by secondary bacterial infections, leading to high economic losses. In 2001 the first human metapneumovirus (hMPV) was isolated and classified as a member of the genus *Metapneumovirus*, which causes respiratory infections in

people. Experimental studies suggest that turkeys also may be susceptible to hMPV. Complete genome sequencing confirmed that the genomic organization of hMPV is similar to that of aMPV. Overall, little is known about the cross-species pathogenicity of these two viruses.

Etiology: aMPV is a member of the family Parainflaviridae and of subfamily Pneumovirinae, which consists of the genus *Pneumovirus* (including the human and bovine respiratory syncytial viruses) and the genus *Metapneumovirus*. Currently the genus *Metapneumovirus* comprises aMPV and hMPV.

Isolates of aMPV are grouped in subtypes A to D. The sequence of the attachment glycoprotein (G protein) can be used to subtype different strains. Based on the phylogenetic analysis of F protein sequences, it was suggested that the European subtypes A, B, and D are all more closely related to each other than to subtype C. More recently, aMPV subtype C isolates were also identified in pheasants in Korea

and water-associated bird species in Europe. The latter was shown to be of a different genetic lineage than the USA subtype C isolates. Irrespective of the differences within subtype C, isolates of this subtype display a higher amino acid sequence homology to hMPV than to European aMPV subtypes A, B, and D.

Transmission and Epidemiology:

The spread of aMPV appears to depend on the poultry population density, standard of hygiene, and biosecurity. Within or between poultry flocks, aMPV may spread rapidly horizontally by direct contact or by contact with contaminated material. aMPV is assumed to be highly contagious. The enveloped virus is rapidly destroyed after release from the host to the environment. Because aMPV affects mainly ciliated epithelial cells of the upper respiratory tract, transmission is most likely to be airborne, especially by aerosol. But ciliated cells of the reproductive tract and possibly macrophages also may be target cells of aMPV. Metapneumovirus subtype C was isolated from eggs of experimentally infected SPF turkeys, but it was suggested that the vertical route may be short-lived and may play only a minor role in viral transmission.

Birds appear to shed aMPV for only a few days after infection. This short period of shedding suggests that there is no latency or carrier status under experimental conditions. There is evidence that on farms aMPV may persist for longer periods. Reconvalescent flocks may be repeatedly reinfected with aMPV within one fattening period.

Clinical Findings: aMPV induces an acute, highly contagious infection of the upper respiratory tract of turkeys and chickens. The disease affects all age groups, although younger birds seem to be more susceptible. In fattening turkeys the upper respiratory tract is predominantly affected, while in laying hens only a mild respiratory infection with a drop in egg production and egg quality has been seen. Coughing associated with lower respiratory tract involvement may lead to prolapses of the uterus in laying turkeys.

Typical respiratory signs in young turkeys include serous, watery nasal and ocular discharge; frothy eyes; and conjunctivitis. At later stages, signs include mucopurulent, turbid nasal discharge; plugged nostrils; swollen infraorbital sinuses; and snicking, sneezing, coughing, or tracheal rales. These respiratory signs are accompanied by depression, anorexia, and ruffled feathers.

The incubation period is 3–7 days, and morbidity in birds of all ages may reach 100%. Mortality may be 1%–30% depending on age and constitution of the flock as well as secondary infections. Birds without secondary infections with good constitution may recover within 7–10 days. However, in birds with secondary infections and under poor management, the disease may be prolonged and exacerbated by airsacculitis, pericarditis, pneumonia, and perihepatitis.

Infection in chickens and pheasants is less clearly defined and may not always be associated with clinical signs. aMPV is associated with swollen head syndrome in chickens. This condition is characterized by swelling of the peri- and infraorbital sinuses, frothy eyes, nasal discharge, torticollis, and opisthotonos due to ear infection. Typically, <4% of the flock is affected, although respiratory signs may be widespread. Mortality is rarely >2%. In broiler breeders and commercial layers, egg production and quality are frequently affected.

Lesions: Macroscopic lesions depend on the course of infection, especially on secondary bacterial infections, and are most prominent on days 4–10 after infection. Gross lesions induced after experimental infection are due to rhinitis, tracheitis, sinusitis, and airsacculitis. Infected birds may be free of gross lesions. Serous to turbid mucus may be observed in the nasal cavity, nasal turbinates, trachea, and in infraorbital sinuses. During the course of infection, the secreted mucus turns from clear and serous to turbid and purulent. Nonspecific signs of inflammation, such as swelling and hyperemia of the mucosa and excessive mucus, can be seen in the upper respiratory tract and in the air sacs. If secondary bacterial infections are present, copious inflammatory exudates are found in the respiratory tract. In addition, pneumonia, pericarditis, perihepatitis, splenomegaly, and hepatomegaly are seen. In the reproductive tract of laying turkeys, lesions can include egg peritonitis, ovary and oviduct regression, folded shell membranes in the oviduct, and misshapen eggs. Microscopic examination of the upper respiratory tract, including the secondary bronchi during the first 2 days after aMPV infection, reveals loss of cilia, increased glandular activity, congestion, and mild mononuclear infiltration of the submucosa. The most pronounced microscopic lesions are found in the mucosa or the nasal turbinates, which may be the most suitable tissue for microscopic evaluation and diagnosis of aMPV infection. Harderian

glands and lacrimal glands may also show infiltration of lymphocytes and formulation of lymphoid follicle-like structures in the interstitial tissue and around the secondary collecting ducts.

Diagnosis: Obtaining samples from the upper respiratory tract of birds in the early stages of the disease is extremely important when attempting virus isolation. Especially in broiler-type chickens, samples should be taken before the sixth day after infection. Once clinical signs are obvious, the isolation of replicating aMPV may not be successful. The most suitable samples for aMPV detection are tracheal and choanal swabs. Tracheal organ cultures prepared from turkey or chicken embryos, or 1- to 2-day-old chicks, are the most sensitive for primary isolation of aMPV. Ciliostasis may occur within 7 days of aMPV A and B but not subtype C inoculation or after passages. The virus has also been isolated after the inoculation of 6- to 8-day-old embryonated chicken or turkey eggs via the yolk sac route and identified by electron microscopy, virus neutralization test, or molecular techniques. Cell cultures have not proved successful for the primary isolation of the virus. However, once the virus has been isolated and adapted in the systems above, it will grow in a variety of avian and mammalian cultures.

Reverse transcriptase PCR (RT-PCR), as well as real-time RT-PCR, tests targeting the F, N, or G gene of aMPV have been developed and are widely used to detect the virus in clinical material, particularly respiratory swabs. Some nested RT-PCR tests have been constructed so that the subtype as well as the identity of virus can be determined from the clinical sample. Based on the growing amount of genome sequence data and access to sequencing techniques, detailed characterization and molecular differentiation of isolated aMPV strains is commonly done. Antigen detection tests have also been developed, including immunofluorescence and immunoperoxidase assays on both fixed and unfixed tissues.

Because of difficulties in isolation and identification of aMPV, serologic assays have been developed to confirm infection in commercial chickens and turkeys. A number of commercial ELISA kits are available and are commonly used, but other techniques, including virus neutralization and indirect immunofluorescence tests, have also been used. Both acute and convalescent serum samples should be submitted for analysis. Although ELISA systems that use either subgroup A or B strains as antigens detect

antibodies to both of these subgroups because of some cross-reactivity, the homologous antigen should be used for the efficient detection of subgroup C. The subtype specificity of the applied test may result in limited or no detection of other subtypes or new emerging aMPV strains that do not cross-react.

Paranynxoviruses (particularly Newcastle disease and parainfluenza virus 3 (see p 2856), infectious bronchitis virus (see p 2909), and influenza viruses (see p 2902) may cause respiratory disease and egg production problems in chickens and turkeys that closely resemble aMPV infection. These viruses can be differentiated on the basis of morphology, hemagglutinating and neuraminidase activity, and molecular characteristics. A wide range of bacteria and *Mycoplasma* spp can cause signs very similar to those of aMPV. These agents are frequently present as secondary opportunistic pathogens and may mask the presence of the aMPV.

Prevention and Treatment: Good management practices can significantly reduce the severity of infection, especially in turkeys; in particular, optimal ventilation, stocking densities, temperature control, litter quality, and biosecurity have a positive influence on the outcome of the disease. Some success in reducing disease severity by controlling secondary bacterial infections with antibiotics has also been reported.

Both live and inactivated vaccines are available for immunization of chickens and turkeys and are widely used in countries where the disease is endemic. Maternal antibodies do not provide sufficient protection against aMPV infection and do not interfere significantly with vaccination. Thus, a vaccination program should plan for the first immunization as soon as possible after hatching. It is crucial to achieve a homogenous state of immunization per flock and farm by application of an adequate vaccine dose to all birds.

Live vaccines, which may be applied by spray or drinking water in the field, stimulate both local respiratory and systemic immunity, and cross-protection between subtypes may occur. But live vaccines may induce only short-lived protection, especially for grow-out of toms, because of the fast decline of local immunity. Thus, repeated revaccination of turkeys is common practice. There is, however, a risk of reversion of the live vaccine strains to more virulent variants. Inactivated aMPV vaccines are often used

for booster immunization of layer and breeder flocks after priming with live vaccines. While inactivated vaccines alone induce only partial protection against aMPV infection, the most efficient and long-lasting protection is achieved by a combined prime-boost vaccination program. This program comprises repeated priming with live attenuated vaccines and booster immunization with inactivated adjuvanted

vaccines. As experimentally shown, in ovo vaccination may also be a promising strategy for effective, early induction of an immune response. Besides live attenuated and classical inactivated vaccines, some genetically engineered viruses, including recombinant vectored vaccines, have been designed and tested under experimental conditions. These have induced partial protection and need further development.

BORDETELLOSIS

(Turkey coryza, *Bordetella avium* rhinotracheitis)

Avian bordetellosis is a highly infectious, acute upper respiratory tract disease of turkeys characterized by high morbidity and usually low mortality. Other synonyms previously used for the disease include *Alcaligenes* rhinotracheitis, adenovirus-associated respiratory disease, acute respiratory disease syndrome, and turkey rhinotracheitis.

Although the disease primarily affects turkeys, quail are also susceptible, and it is an opportunistic infection in chickens. Damage to the upper respiratory tract from prior exposure to an upper respiratory disease agent or vaccine such as infectious bronchitis virus or Newcastle disease virus, or from an environmental irritant such as ammonia, is necessary to induce signs in chickens.

Bordetellosis has been identified in almost every area of the world where turkeys are intensively reared. Historically, it has been severe in focal areas and rare or nonapparent in other locations. The reasons for these epidemiologic differences are not known.

Etiology and Pathogenesis: The causative agent is *Bordetella avium*, a gram-negative, nonfermentative, motile, aerobic bacillus. It can be grown using many different media, including MacConkey agar, Bordet-Gengou agar, veal infusion broth, trypticase soy broth, blood agar, and brain-heart infusion broth. Strains of *B. avium* typically produce small (0.2–1 mm diameter after 24 hr incubation), compact, translucent, glistening pearl-like colonies with smooth edges. After serial passage in the laboratory, a rough colony type with a dry appearance and a serrated, irregular edge can be observed for some isolates. Rough colonies represent a global suppression of virulence factors in *B. avium* termed antigenic variation and are

nonpathogenic. When the bacillus is grown in broth media high in nutrients, filamentous forms can be observed.

The mechanism of pathogenesis involves the ability of *B. avium* to destroy ciliated epithelial cells in the trachea. Certain strains of the bacteria adhere to the ciliated pseudostratified columnar epithelium and produce toxins, some of which appear to be similar to those from other *Bordetella* spp. Toxins associated with pathogenic strains of *B. avium* include a heat-labile toxin, tracheal cytotoxin, dermonecrotic toxin, and osteotoxin. Adherence factors associated with the bacterium include the hemagglutinin Baa1 autotransporter protein and possibly pili and components associated with lipopolysaccharide. Damage to the tracheal cartilage with distortion and discoloration of the tracheal rings is often observed and thought to be caused by the cytotoxin and/or the osteotoxin. Some mortality is due to suffocation from

Scanning electron microscopy of a trachea from a poult 3 days after *Bordetella avium* infection; note numerous *B. avium* cells attached to ciliated columnar epithelial cells. Courtesy of Dr. Mark W. Jackwood.

increased mucus production in the trachea and tracheal collapse. As with many bacterial infections, iron acquisition is necessary for colonization and spread of *B. avium* in the host. Virulence factor expression is globally controlled by a virulence gene locus in response to environmental conditions that favor antigenic variation among *B. avium* isolates.

Damage to the upper respiratory tract can lead to secondary infections with *Escherichia coli* or other agents, which can significantly increase the severity of the disease. In many cases, turkeys infected solely with *B. avium* recover within 4–6 wk without serious consequences.

Epidemiology and Transmission: Morbidity is usually 80%–100% in young turkeys. Mortality can range from 0% in birds with uncomplicated disease to >40% if secondary invaders are present. Mortality can increase and signs can become severe if young turkeys infected with *B. avium* also become infected with other agents (eg, *E. coli*, Newcastle disease virus) or when environmental conditions in turkey barns are less than optimal. Bordetellosis is a major initiator of colibacillosis in turkeys. There is an age-related resistance to the disease. Turkeys >4–5 wk old are most often refractory to the disease but not infection, and thus can be a factor in spread of the bacterium.

B. avium is highly contagious and easily transmitted from infected turkeys to susceptible birds by direct contact. It can also be transmitted through contaminated drinking water, feed, and litter, which can remain infectious for 1–6 mo.

Clinical Findings: Signs of the disease usually occur 7–10 days after infection and include sinusitis with a clear nasal discharge that can be observed when pressure is applied to the nares. Foamy-water eyes, a snick or cough, mouth breathing, dyspnea, tracheal rales, and altered vocalization are also characteristic. Complicated disease can result in more exaggerated signs including airsacculitis.

Lesions: Lesions are primarily found in the upper respiratory tract and consist of nasal and tracheal exudates, collapse of cartilaginous rings, and progressive loss of ciliated epithelium. In uncomplicated disease, the tracheal epithelium can return to normal 4–6 wk after the onset of signs.

At necropsy, turkeys with characteristic bordetellosis have watery eyes and extensive mucus in the sinuses and trachea, which rarely extends below the tracheal

bifurcation. The lining of the trachea may have extremely mild hemorrhage in some cases, and softening of the tracheal rings is usually felt. In addition, a dorsal/ventral flattening of the trachea can sometimes be observed. Pneumonia and airsacculitis are observed only when the disease is complicated by another disease agent.

Diagnosis: Diagnosis of infection is confirmed by isolation of *B. avium* on MacConkey agar and identification using standard biochemical assays. Nonfermenting, small, slow-growing colonies from specimens from the anterior trachea are typical. The bacterium is best isolated from the anterior trachea; cultures taken from the sinuses frequently become overgrown with other, faster-replicating bacteria such as *Proteus* spp.

Serology is also important, and both microagglutination (detects IgM) and ELISA (detects IgG) tests are available. The microagglutination test can detect specific antibodies ~1 wk after infection. The ELISA test generally detects specific antibodies >2 wk after infection and has the added benefit of detecting maternal antibody. Monoclonal antibody-based agglutination and indirect immunofluorescent tests as well as PCR tests have also been used to identify *B. avium*.

Other nonfermenters, *B. bronchiseptica* and *B. hinzei*, which are for the most part nonpathogenic, can sometimes be isolated from the trachea and must be differentiated from *B. avium*. Pathogenic *B. avium* can be differentiated by growth and colony morphology on MacConkey agar; no growth on minimal essential medium, a negative urease reaction, and hemagglutination of guinea pig erythrocytes. *B. avium* also agglutinates chicken and turkey erythrocytes.

Treatment: Treatment with antimicrobial agents by aerosol, injection, or in the water has not been effective, even though *B. avium* may be highly sensitive. The tracheal epithelium of the turkey is a difficult location to medicate even though blood levels of the antimicrobial appear to be adequate. Resistance to streptomycin, sulfonamides, and tetracycline can be carried on plasmids and has been observed for some strains of *B. avium*. Antimicrobial therapy may be helpful for secondary colibacillosis.

Control and Prevention: Vaccination with bacterins and a live temperature-sensitive mutant vaccine have given mixed results depending on the age of the turkey and the method of administration.

Typically, turkeys >3 wk old respond positively to vaccination with the live temperature-sensitive vaccine. Vaccination is not widely practiced by turkey breeders, and the immunity that is passed to progeny generally comes from natural infections.

B. avium is easily carried between farms. Thus, prevention should include a good biosecurity program. Rigorous cleanup

and disinfection after field outbreaks is essential. Most of the commonly used disinfectants are effective.

Zoonotic Risk: *B. avium* may be a rare opportunistic pathogen in people. In addition, a closely related organism, *B. hinzii*, also isolated from poultry, has been associated with septicemia and bacteremia in older or immunocompromised people.

INFECTIOUS BRONCHITIS

Infectious bronchitis is an acute, highly contagious disease of major economic importance in commercial chicken flocks throughout the world. It is usually characterized by respiratory signs, although decreased egg production and poor egg quality are sometimes seen in breeders and layers. Some strains of the etiologic agent, infectious bronchitis virus (IBV), are nephropathogenic, causing interstitial nephritis, particularly in chicks. Associations with myopathy and proventriculitis have also been reported.

Etiology and Epidemiology: IBV is a coronavirus that only causes disease in chickens, although some other birds may be subclinically infected. Some serotypes are geographically restricted, but multiple serotypes commonly cocirculate in one geographic region. In recent years, a novel IBV genotype, the QX strain, has become increasingly common in Asia and Europe. IBV is shed by infected chickens in respiratory discharges and feces, and it can be spread by aerosol, ingestion of contaminated feed and water, and contact with contaminated equipment and clothing. Naturally infected chickens and those vaccinated with live IBV may shed virus intermittently for up to 20 wk after infection. The incubation period is generally 24–48 hr, with the peak in excretion of virus from the respiratory tract lasting 3–5 days after infection. The severity of disease and the body systems involved are influenced by the strain of the virus; the age, strain, immune status, and diet of the chickens; and cold stress. In addition, coinfection with *Mycoplasma gallisepticum*, *Mycoplasma synoviae*, *Escherichia coli*, and/or *Avibacterium paragallinarum* can exacerbate disease.

Clinical Findings: Morbidity is commonly close to 100%. Chicks may cough, sneeze, and

have tracheal rales for 10–14 days. Conjunctivitis and dyspnea may be seen, and sometimes facial swelling, particularly with concurrent bacterial infection of the sinuses. Chicks may appear depressed and huddle under heat lamps. Feed consumption and weight gain are reduced. Infection with nephropathogenic strains can cause initial respiratory signs, then later depression, ruffled feathers, wet droppings, greater water intake, and death. In layers, egg production may drop by as much as 70%, and eggs are often misshapen, with thin, soft, rough, and/or pale shells, and can be smaller and have watery albumen. In most cases, egg production and egg quality return to normal, but this may take up to 8 wk. In most outbreaks mortality is 5%, although mortality rates are higher when disease is complicated by concurrent bacterial infection. Nephropathogenic strains can induce interstitial nephritis with high mortality (up to 60%) in young chicks. Infection of young chicks may cause permanent damage to the oviduct, resulting in layers or breeders that never reach normal levels of production.

Lesions: In the respiratory tract, the trachea, sinuses, and nasal passages may contain serous, catarrhal, or caseous exudates, and the air sacs a foamy exudate initially, progressing to cloudy thickening. If complicated by infection with *E. coli*, there may be caseous airsacculitis, perihepatitis, and pericarditis. Birds infected when very young may have cystic oviducts, whereas those infected while in lay have an oviduct of reduced weight and length and regression of the ovaries. Infection with nephropathogenic strains results in swollen, pale kidneys, with the tubules and ureters distended with urates; in birds with urolithiasis, the ureters may be distended with urates and contain uroliths, and the kidneys may be atrophied.

Diagnosis: Laboratory confirmation is required for diagnosis of respiratory forms because of similarities to mild forms of disease caused by agents such as Newcastle disease virus, avian metapneumovirus, infectious laryngotracheitis virus, mycoplasmas, *A. paragallinarum*, and *Ornithobacterium rhinotracheale*. Demonstration of seroconversion or a rise in antibody titer against IBV by ELISA, or hemagglutination inhibition or virus neutralization tests can be used for diagnosis when there is a history of respiratory disease or reduced egg production.

Definitive diagnosis is generally based on virus detection and identification. Virus can be isolated by inoculation of homogenates of tracheal, cecal tonsil, and/or kidney tissue into 9- to 11-day-old SPF chicken embryos, with growth of IBV indicated by embryo stunting and curling, and deposition of urates in the mesonephros, with variable mortality. Alternatively, IBV may be isolated in tracheal organ cultures, with growth of virus indicated by cessation of ciliary motility. Several blind passages of the virus may be necessary for isolation of some field strains. More rapid diagnosis may be achieved using reverse transcriptase-polymerase chain reaction (RT-PCR) assays to detect viral RNA in nucleic acid extracts of tracheal, cecal tonsil, or kidney tissue.

Typing viruses can help distinguish vaccine and field strains and may help diagnose outbreaks caused by serotypes distinct from those of the vaccines used in a flock. Serotypes have been identified using sera from SPF chickens inoculated with known serotypes in virus neutralization tests. However, because this is expensive and time consuming, it is not readily available. A restricted range of serotype-specific monoclonal antibodies (MAb) have been developed for serotyping, but direct detection viral antigen using these MAbs to immunohistochemically stain tissue sections from diseased birds is of limited value because of the low concentration of antigen in tissues. The MAbs have been best used after propagation in chicken embryos, to detect viral antigen in the chorioallantoic membranes by immunofluorescence or immunoperoxidase staining, or in the allantoic fluid by ELISA. Analyses of the products of RT-PCR assays are now commonly used to identify the virus serotype and to identify individual strains within serotypes. The S1 region of the spike glycoprotein gene determines the serotype, and RT-PCR products derived from this region can be subjected to restriction fragment length polymorphism analysis,

analyzed by nucleotide sequencing, or compared with reference strains using high-resolution melting curve analysis. Genotype determination based on the S1 region can be complemented by analyzing other regions of the viral genome, including the nucleocapsid gene and the 5' untranslated region. These analyses can also aid in rapid detection of novel recombinant IBVs.

Control: No medication alters the course of IBV infection, although antimicrobial therapy may reduce mortalities caused by complicating bacterial infections. In cold weather, increasing the ambient temperature may reduce mortalities, and reducing the protein concentrations in feed and providing electrolytes in drinking water may assist in outbreaks caused by nephropathogenic strains.

The attenuated vaccines used for immunization may produce mild respiratory signs. These vaccines are initially given to 1- to 14-day-old chicks by spray, drinking water, or eye drop, and birds are commonly revaccinated. Revaccination with a virus from a distinct serotype can induce broader protection. Attenuated or adjuvanted inactivated vaccines can be used in breeders and layers to prevent egg production losses.

There are many distinct serotypes of IBV, and new or variant serotypes, which are not fully controlled by existing vaccines, are identified relatively frequently. Some variants may be derived from recombination between existing field strains and vaccine strains, whereas others result from point mutations in existing strains. Selection of vaccines should be based on knowledge of the most prevalent serotype(s) on the premises. The correlation between serotype and protection is imperfect, and definition of the most appropriate vaccine, or combination of vaccines, may require experimental assessment of several combinations of vaccines to identify the most effective regimen. The most commonly used live vaccines in the USA contain derivatives of the Massachusetts, Connecticut, and Arkansas strains, whereas in Australia, where the most prevalent serotypes are distinct from most other countries, vaccines are based on derivatives of the VicS and Armidale strains. In Europe, vaccines incorporating derivatives of the 4/91 strain and those derived from QX-like viruses are available. Vaccination with selected variant serotypes may be of use when these variants are the dominant strain in flocks, although regulatory authorities in some countries only permit use of vaccines derived from the Massachusetts strain.

INFECTIOUS CORYZA

Infectious coryza is an acute respiratory disease of chickens characterized by nasal discharge, sneezing, and swelling of the face under the eyes. It is found worldwide. The disease is seen only in chickens; reports of the disease in quail and pheasants probably describe a similar disease that is caused by a different etiologic agent.

In developed countries such as the USA, the disease is seen primarily in pullets and layers and occasionally in broilers. In the USA, it is most prevalent in commercial flocks in California and the southeast, although the northeastern USA has experienced significant outbreaks. In developing countries, the disease often is seen in very young chicks, even as young as 3 wk old. Poor biosecurity, poor environment, and the stress of other diseases are likely reasons why infectious coryza is more of a problem there. The disease has no public health significance.

Etiology: The causative bacterium is *Avibacterium paragallinarum*, a gram-negative, pleomorphic, nonmotile, catalase-negative, microaerophilic rod that requires nicotinamide adenine dinucleotide (V-factor) for in vitro growth. When grown on blood agar with a staphylococcal nurse colony that excretes the V-factor, the satellite colonies appear as dewdrops, growing adjacent to the nurse colony. V-factor-independent *Av paragallinarum* have been recovered in South Africa and Mexico. The most commonly used serotyping scheme is the Page scheme, which groups *Av paragallinarum* isolates into three serovars (A, B, and C) that correlate with immunotype specificity.

Epidemiology and Transmission:

Chronically ill or healthy carrier birds are the reservoir of infection. Chickens of all ages are susceptible, but susceptibility increases with age. The incubation period is 1–3 days, and the disease duration is usually 2–3 wk. Under field conditions, the duration may be longer in the presence of concurrent diseases, eg, mycoplasmosis.

Infected flocks are a constant threat to uninfected flocks. Transmission is by direct contact, airborne droplets, and contamination of drinking water. “All-in/all-out” management has essentially eradicated infectious coryza from many commercial poultry establishments in the USA.

Commercial farms that have multiple-age flocks tend to perpetuate the disease. Egg transmission does not occur. Molecular techniques such as restriction endonuclease analysis and ribotyping have been used to trace outbreaks of infectious coryza.

Clinical Findings: In the mildest form of the disease, the only signs may be depression, a serous nasal discharge, and occasionally slight facial swelling. In the more severe form, there is severe swelling of one or both infraorbital sinuses with edema of the surrounding tissue, which may close one or both eyes. In adult birds, especially males, the edema may extend to the intermandibular space and wattles. The swelling usually abates in 10–14 days; however, if secondary infection occurs, swelling can persist for months. There may be varying degrees of rales depending on the extent of infection. In Argentina, a septicemic form of the disease has been reported, probably due to concurrent infections. Egg production may be delayed in young pullets and severely reduced in producing hens. Birds may have diarrhea, and feed and water consumption usually is decreased during acute stages of the disease.

Lesions: In acute cases, lesions may be limited to the infraorbital sinuses. There is a copious, tenacious, grayish, semifluid exudate. As the disease becomes chronic or other pathogens become involved, the sinus exudate may become consolidated and turn yellowish. Other lesions may include conjunctivitis, tracheitis, bronchitis, and airsacculitis, particularly if other pathogens are involved. The histopathologic response of respiratory organs consists of disintegration and hyperplasia of mucosal and glandular epithelia and edema with infiltration of heterophils, macrophages, and mast cells.

Diagnosis: Isolation of a gram-negative, satellitic, catalase-negative organism from chickens in a flock with a history of a rapidly spreading coryza is diagnostic. The catalase test is essential, because nonpathogenic hemophilic organisms, which are catalase-positive, are present in both healthy and diseased chickens. A PCR test that can be used on the live chicken and that has proved superior to culture, even in developing countries, has been developed. A real-time version of the PCR is also available.

Production of typical signs after inoculation with nasal exudate from infected into susceptible chickens is also reliable diagnostically. No suitable serologic test exists; a hemagglutination-inhibition test is the best of those available. Swelling of the face and wattles must be differentiated from that seen in fowl cholera (see p 2822). Other diseases that must be considered are mycoplasmosis, laryngotracheitis, Newcastle disease, infectious bronchitis, avian influenza, swollen head syndrome (ornithobacteriosis), and vitamin A deficiency.

While currently found only in South Africa and Mexico, the presence of a V-factor-independent *Av paragallinarum* must also be considered. The *Av paragallinarum* PCR is an ideal diagnostic tool in this situation.

Control and Treatment: Prevention is the only sound method of control. "All-in/all-out" farm programs with sound management and isolation methods are the best way to avoid infectious coryza. Replacements should be raised on the same farm or obtained from clean flocks. If replacement pullets are to be placed on a farm that has a history of infectious coryza, bacterins are available to help prevent and control the disease. USDA-licensed bacterins are available, and bacterins also are produced within states for intrastate use. Bacterins also are produced in many other countries.

Because serovars A, B, and C are not cross-protective, it is essential that bacterins contain the serovars present in the target population. Vaccination should be completed ~4 wk before infectious coryza usually breaks out on the individual farm. Antibodies detected by the hemagglutination-inhibition test after bacterin administration do not necessarily correlate with protective immunity. Controlled exposure to live organisms also has been used to immunize layers in endemic areas.

Because early treatment is important, water medication is recommended immediately until medicated feed is available. Erythromycin and oxytetracycline are usually beneficial. Several new-generation antibiotics (eg, fluoroquinolones, macrolides) are active against infectious coryza. Various sulfonamides, sulfonanide-trimethoprim, and other combinations have been successful. Antibiotic use in chickens is subject to national regulations that vary from country to country, and use and efficacy of the various antibiotics must be reviewed in the light of the relevant national regulations. In more severe outbreaks, although treatment may result in improvement, the disease may recur when medication is discontinued.

Preventive medication may be combined with a vaccination program if started pullets are to be reared or housed on infected premises.

INFECTIOUS LARYNGOTRACHEITIS

Infectious laryngotracheitis (ILT) is an acute, highly contagious, herpesvirus infection of chickens and pheasants characterized by severe dyspnea, coughing, and rales. It can also be a subacute disease with nasal and ocular discharge, tracheitis, conjunctivitis, and mild rales. The disease is caused by *Gallid herpesvirus 1*, commonly known as infectious laryngotracheitis virus (ILTV). It has been reported from most areas of the USA in which poultry are intensively reared, as well as from many other countries.

Clinical Findings: In the acute form, gasping, coughing, rattling, and extension of the neck during inspiration are seen 5–12 days after natural exposure. Reduced productivity is a varying factor in laying flocks. Affected birds are anorectic and

inactive. The mouth and beak may be bloodstained from the tracheal exudate. Mortality varies but may reach 50% in adults and is usually due to occlusion of the trachea by hemorrhage or exudate. Signs usually subside after ~2 wk, although some birds may show signs for longer periods. Strains of low virulence produce little or no mortality with mild respiratory signs and a slight decrease in egg production.

After recovery, birds remain carriers for life and become a source of infection for susceptible birds. The latent virus can be reactivated under stressful conditions. Infection also may be spread mechanically. Several epidemics have been traced to the transport of birds in contaminated crates, and the practice of litter spread in pastures is believed to be related to epidemics of the disease.

Diagnosis: The acute disease is characterized by the presence of blood, mucus, yellow caseous exudates, or a hollow caseous cast in the trachea. Microscopically, a desquamative, necrotizing tracheitis is characteristic of acute disease. In the subacute form, punctiform hemorrhagic areas in the trachea and larynx and mild conjunctivitis with lacrimation may be detected. A rapid diagnosis can be achieved by detection of intranuclear inclusion bodies in the tracheal epithelium early in the course of the disease; results of the microscopic examination can be rapidly confirmed by detection of viral DNA using virus-specific PCR assays. Isolation and identification of the virus is done in chicken embryos or tissue culture from embryo liver or kidney cells or from kidney cells from adult chickens. Chicken embryos are preferred for virus isolation. Chorioallantoic membrane of developing chicken embryos (9–12 days old) is inoculated with the specimen. Microscopic examination of the chorioallantoic membrane lesion shows intranuclear inclusions. On microscopic examination of the trachea, intranuclear inclusion lesions produced by ILTV infection must be differentiated from the

diphtheritic form of fowlpox infection that produces intracytoplasmic inclusions.

Field isolates and vaccine strains of ILTV are routinely differentiated by PCR amplification of single or multiple ILTV genome areas, followed by sequencing of the PCR products and comparative analysis of the sequences obtained. More recently, field isolates and vaccine strains have been differentiated more accurately by full genome sequencing analysis.

Control: In endemic areas and on farms where a specific diagnosis is made, the disease is controlled by implementation of biosecurity measures and vaccination. Vaccination is done with live attenuated vaccines and viral vector recombinant vaccines. Live vaccines originated from virulent isolates that were attenuated by consecutive passages in embryos or tissue culture. These are applied via eye drop or through mass vaccination by water or spray. Viral vector recombinant vaccines in fowlpox and herpesvirus of turkeys have been designed to express ILTV immunogenic proteins and are administered to individual birds by in ovo, SC, or wing-web vaccination.

QUAIL BRONCHITIS

Quail bronchitis is a naturally occurring, highly contagious, often fatal respiratory disease of bobwhite quail, seen both in the wild and in captivity. The disease is of major economic significance to gamebird breeders and has a worldwide distribution. It is a serious disease on certain farms where quail are pen-raised, and particularly when quail of different ages are maintained on the same premises.

The causative agent, quail bronchitis virus, is a Group I serotype 1 avian adenovirus that can be readily isolated from the respiratory tract of acutely affected birds. The virus is also easily isolated from fecal samples, intestine, liver, and occasionally the bursa of Fabricius. It is highly contagious and spreads rapidly through multiple-age units. Other avian species, particularly chickens, may be carriers.

Clinical signs include respiratory distress, coughing, sneezing, rales, and nasal or ocular discharge. Loose, watery droppings are common in some acutely affected older

birds. Conjunctivitis, mild to severe tracheitis (the trachea may be completely filled with mucus), airsacculitis, hepatitis, and gaseous distention of the intestines may be seen. Multiple pale, pinpoint (3 mm) foci of necrosis in the liver and mottling and enlargement of the spleen are common lesions in infected birds. Mortality may reach 100% in birds <2 wk old but is usually <25% in birds >4 wk old.

The disease is often self-limiting. Experimental vaccines have proved ineffective in preventing quail bronchitis. There is no specific treatment, but increasing the brooder temperature by 3°–5°F (1.5°–3°C), preventing “piling up,” and avoiding contact between older and younger birds and other avian species are of value, as are strict isolation and sanitation. Immunity is long lasting, possibly for life, and recovered birds can be retained for breeders. New birds should not be introduced to premises without a 30-day quarantine.

NUTRITION AND MANAGEMENT: POULTRY

NUTRITIONAL REQUIREMENTS

Poultry convert feed into food products quickly, efficiently, and with relatively low environmental impact compared with other livestock. The high rate of productivity of poultry results in relatively high nutrient needs. Poultry require the presence of at least 38 dietary nutrients in appropriate concentrations and balance. The nutrient requirement figures published in *Nutrient Requirements of Poultry* (National Research Council, 1994) are the most recent available and should be viewed as minimal nutrient needs for poultry. They are derived from experimentally determined levels after an extensive review of the published data. Criteria used to determine the requirement for a given nutrient include growth, feed efficiency, egg production, prevention of deficiency symptoms, and quality of poultry product. These requirements assume the nutrients are in a highly bioavailable form, and they do not include a margin of safety. Consequently, adjustments should be made based on bioavailability of nutrients in various feedstuffs. A margin of safety should be added based on the length of time the diet will be stored before feeding, changes in rates of feed intake due to environmental temperature or dietary energy content, genetic strain, husbandry conditions (especially the level of sanitation), and the presence of stressors (such as diseases or mycotoxins).

Water: Water is an essential nutrient. Many factors influence water intake, including environmental temperature, relative humidity, salt and protein levels of the diet, birds' productivity (rate of growth or egg production), and the individual bird's ability to resorb water in the kidney. As a result, precise water requirements are highly variable. Water deprivation for ≥ 12 hr has an adverse effect on growth of young poultry and egg production of layers; water deprivation for ≥ 36 hr results in a marked increase in mortality of both young and mature poultry. Cool, clean water, uncontaminated by high levels of minerals or other potential toxic substances, must be available at all times.

Energy Requirements and Feed Intake: The energy requirements of

poultry and the energy content of feedstuffs are expressed in kilocalories (1 kcal equals 4.1868 kilojoules). Two different measures of the bioavailable energy in feedstuffs are in use, metabolizable energy (AME_n) and the true metabolizable energy (TME_n). AME_n is the gross energy of the feed minus the gross energy of the excreta after a correction for the nitrogen retained in the body. Calculations of TME_n make an additional correction to account for endogenous losses of energy that are not directly attributable to the feedstuff and are usually a more useful measure. AME_n and TME_n are similar for many ingredients. However, the two values differ substantially for some ingredients such as feather meal, rice, wheat middlings, and corn distiller's grains with solubles.

Poultry can adjust their feed intake over a considerable range of feed energy levels to meet their daily energy needs. Energy needs and, consequently, feed intake also vary considerably with environmental temperature and amount of physical activity. A bird's daily need for amino acids, vitamins, and minerals are mostly independent of these factors. The nutrient requirement values in the following tables are based on typical rates of intake of birds in a thermoneutral environment consuming a diet that contains a specific energy content (eg, 3,200 kcal/kg for broilers). If a bird consumes a diet that has a higher energy content, it will decrease its feed intake; consequently, that diet must contain a proportionally higher amount of amino acids, vitamins, and minerals. Thus, nutrient density in the ration should be adjusted to provide appropriate nutrient intake based on requirements and the actual feed intake.

Because of the ability of poultry to adjust their feed intake to accommodate a wide range of diets with differing energy content, the energy values listed in the nutrient requirement tables in this section (see TABLES 6–15) should be regarded as guidelines rather than absolute requirements.

Appropriate body weight and fat deposition are important factors in rearing pullets for maximal egg production. Most strains of White Leghorn chickens have relatively low body weights and do not tend, under normal feeding, to become obese. Feed is normally provided for ad lib intake to this strain of pullets. For brown-egg strains

of chickens, some degree of restriction is often practiced (~90% of ad lib feeding) to prevent precocial onset of lay. Broiler strains tend to become obese if fed ad lib; feed restriction is necessary for broiler pullets and broiler breeders. When feed restriction is practiced, the feed levels of amino acids, vitamins, and minerals must be proportionally increased to prevent deficiencies. Most large commercial breeders provide feed

restriction and dietary nutrient guidelines specific for their strains.

Amino Acid Requirements: Poultry, like all animals, synthesize proteins that contain 20 L-amino acids. Birds are unable to synthesize 9 of these amino acids because of the lack of specific enzymes: arginine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and

TABLE 6 NUTRIENT REQUIREMENTS OF GROWING PULLETS^a

Age (wk)	0–6	6–12	12–18	18 to 1st Egg

^a Requirements are listed as percentages of diet.

valine, Histidine, glycine, and proline can be synthesized by birds, but the rate is usually insufficient to meet metabolic needs and a dietary source is required. These 12 amino acids are referred to as the essential amino acids. Tyrosine and cysteine can be synthesized from phenylalanine and methionine, respectively, and are referred to as conditionally essential because they must be in the diet if phenylalanine or methionine levels are inadequate. The diet must also supply sufficient amounts of nitrogen to allow the synthesis of nonessential amino acids. Essential amino acids are often

added to the diet in purified form (eg, DL-methionine and L-lysine) to minimize the total protein level as well as the cost of the diet. This has the added advantage of minimizing nitrogen excretion.

Vitamins: Requirements for vitamins A, D, and E are expressed in IU. For chickens, 1 IU of vitamin A activity is equivalent to 0.3 mcg of pure retinol, 0.344 mcg of retinyl acetate, or 0.6 mcg of β -carotene. However, young chicks use β -carotene less efficiently.

One IU of vitamin D is equal to 0.025 mcg of cholecalciferol (vitamin D₃). Ergocalciferol

TABLE 8 NUTRIENT REQUIREMENTS OF BROILERS^a

Age ^b	0–3 wk	3–6 wk	6–8 wk
kcal AME ₁₈ /kg diet ^c	3,200	3,200	3,200
Crude protein ^d	23.00	20.00	18.00

Lysine ^e	1.10	1.00	0.85
Methionine	0.50	0.38	0.32
Methionine + cystine	0.90	0.72	0.60
Phenylalanine	0.72	0.65	0.56
Phenylalanine + tyrosine	1.34	1.22	1.04
Proline	0.60	0.55	0.46
Threonine	0.80	0.74	0.68
Tryptophan	0.20	0.18	0.16
Valine	0.90	0.82	0.70

^a Requirements are listed as percentages of diet.

^b The 0- to 3-, 3- to 6-, and 6- to 8-wk intervals for nutrient requirements are based on chronology for which research data were available; however, these nutrient requirements are often implemented at younger age intervals or on a weight-of-feed consumed basis.

^c These are typical dietary energy concentrations. Different energy values may be appropriate depending on local ingredient prices and availability.

^d Broiler chickens do not have a requirement for crude protein per se. However, there should be sufficient crude protein to ensure an adequate nitrogen supply for synthesis of nonessential amino acids. Suggested requirements for crude protein are typical of those derived with corn-soybean meal diets, and levels can be reduced when synthetic amino acids are used.

^e Recent research has shown that higher levels of lysine are needed for maximal growth and efficiency of modern broilers.

(vitamin D₂) is used with an efficiency of <10% of vitamin D₃ in poultry.

One IU of vitamin E is equivalent to 1 mg of synthetic DL- α -tocopherol acetate. Vitamin E requirements vary with type and level of fat in the diet, the levels of selenium and trace minerals, and the presence or absence of other antioxidants. When diets high in long-chain highly polyunsaturated fatty acids are fed, vitamin E levels should be increased considerably.

Choline is required as an integral part of the body phospholipid, as a part of acetylcholine, and as a source of methyl groups. Growing chickens can also use betaine as a methylating agent. Betaine is

widely distributed in practical feedstuffs and can spare the requirement for choline but cannot completely replace it in the diet.

All vitamins are subject to degradation over time, and this process is accelerated by moisture, oxygen, trace minerals, heat, and light. Stabilized vitamin preparations and generous margins of safety are often applied to account for these losses. This is especially true if diets are pelleted, extruded, or stored for long periods.

Minerals: Much of the phosphorus in feedstuffs of plant origin is complexed by phytate and is not absorbed efficiently by poultry. Consequently, it is critical that only

the available phosphorus and not the total phosphorus levels be considered. Appropriate calcium nutrition depends on both the level of calcium and its ratio to that of available phosphorus. For growing poultry, this ratio should not deviate substantially from 2:1. The calcium requirement of laying hens is very high and increases with the rate of egg production and age of the hen.

Other Nutrients and Additives: The chick has requirements for 38 nutrients, together with an adequate level of metabo-

lizable energy and water. Some additional nutrients may be necessary for growth and development under certain conditions. These include vitamin C, pyrroloquinoline quinone, and several heavy metals.

Non-nutrient antioxidants, such as ethoxyquin, are usually added to poultry diets to protect vitamins and unsaturated fatty acids from oxidation. Antibiotics at low levels (5-25 mg/kg of feed, depending on the antibiotic) and surfeit copper (150 ppm) are sometimes included to improve growth rate and feed efficiency. Enzymes

that increase the bioavailability of dietary phosphorus, energy, and protein are often used in poultry diets when their costs are not prohibitive. In some cases, phytase enzymes are used to decrease the amount of phosphorus in the excreta to meet environmental regulations.

FEEDING AND MANAGEMENT PRACTICES

Success of the feeding program should be measured by how it achieves the breeder's goals for proper weight and development specific to each strain. Feed and the length of time required to attain certain weights in pullets and turkeys are presented in the growth and feed tables elsewhere in this chapter (*see* p 2914). The figures in these tables can be used as a guide to estimate the amount of feed required but will vary

considerably because of differences in the nutrient density of feed, strain or breed of bird, amount of feed wasted, and environmental temperature.

Most diets used to feed poultry are nutritionally "complete" and commercially mixed, ie, prepared by feed manufacturing companies, most of which employ trained nutritionists. The formulation and mixing of poultry feeds requires knowledge and experience in purchasing ingredients, experimental testing of formulas, laboratory control of ingredient quality, and computer applications. Improper mixing can result in vitamin and mineral deficiencies, lack of protection against disease, or drug toxicity.

The physical form of the feed influences the expected results. Most feeds for starting and growing birds are produced as pellets or crumbles. In the pelleting process, the mash is treated with steam and then passed through a suitably sized die under pressure.

TABLE 11 NUTRIENT REQUIREMENTS OF BOBWHITE QUAIL^a

^a Requirements are listed as percentages or as mg/kg of diet. For values not listed, see REQUIREMENTS OF LAYING HENS (TABLE 7) and LEGHORN-TYPE CHICKENS (TABLE 14) as a guide.

^b These are typical dietary energy concentrations.

Adapted, with permission, from *Nutrient Requirements of Poultry*, 1994, National Academy of Sciences, National Academy Press, Washington, DC.

The pellets are then cooled quickly and dried by means of a forced air draft. The conditions under which pelleting occurs (eg, use of an expander rather than an extruder, exposure to high temperature, use of soft pellets) have an important effect on the nutritional quality of the pellets or of the crumbles produced by crushing the pellets.

FEEDING METHODS

For newly hatched birds of any species, a "complete" feed in crumble form is the program of choice, regardless of other considerations. A "complete" feed program for growing stock, particularly for laying and breeding stock, is also highly recommended. Advantages of the "complete" feed program over the "mash and grain" system include the simplicity of feeding, accuracy of medication, improved balance of dietary nutrients, and superior feed conversion efficiency.

Regardless of the system of feeding, recommendations of the feed manufacturer

or the strain's breeder company should be followed with regard to the feeding of extra calcium, grit, or whole grain. Fresh, clean water should always be readily available.

VACCINATION PROGRAMS

See TABLES 16–21 for recommended vaccination programs for broilers, broiler-breeders, commercial layers, turkeys, duck breeders, and commercial ducklings.

MANAGEMENT OF GROWING CHICKENS

Broiler houses generally have specific areas designated for brooding. These areas could be throughout the whole house but with rings of cardboard (often referred to as chick guards) used to keep chicks around a heat source; more commonly, an area of the house is curtained off and preheated before chick placement. Either way, the brooder area floor temperature should be between

TABLE 12 NUTRIENT REQUIREMENTS OF PEKIN DUCKS^a

85°–90°F (29.4°–32.2°C). As the birds become older, the brooder temperature is lowered 5°F (2.8°C) each week until it is 70°F (21.1°C). At ~1 wk of age, the chick guards are removed or the curtains are opened, and the chicks have access to the additional space in the house. In particularly large chicken houses, there may be a second area curtained off for several days (up to 10–14 days of age) before the chicks are given access to the complete house. Ample space should be provided for feeders and waterers, which should be well distributed in the house.

At least 3 in. (7.5 cm) of suitable litter, clean for each brood and spread to an even depth, should be provided at the start. Litter must be free of mold; it should absorb moisture without caking, be nontoxic, and of large enough particle size to discourage consumption. Chicks are started with 24 hr of light for several days; thereafter, light is reduced. Both length of day and intensity of light are important. Lighting programs vary widely, depending on whether housing is windowless or open-sided, and should comply with recommendations of major breeders in similar situations.

^b These are typical dietary energy concentrations.

^a Adapted, with permission, from *Nutrient Requirements of Poultry*, 1994, National Academy of Sciences, National Academy Press, Washington, DC.

When rearing pullets to be used as commercial egg laying or meat type breeding hens, feeding systems are often combined with day-length control during rearing to influence the rate at which birds mature. Under certain conditions, pullets may be beak trimmed at the hatchery or, in rare cases, within the first 7 days after hatch. In controlled environment housing, day lengths are controlled more precisely; with dim lights, beak trimming may be delayed until later in the growing period.

Pullets should be treated for external and internal parasites as required. Vaccination should be used to control problem diseases of the geographic area (see p 2920).

Many commercial egg laying type pullets are reared in cages. The cage manufacturer usually supplies specific instructions regarding heating, bird density, and feeding space. Most commercial rations are fortified with sufficient nutrients to meet the requirements of cage-reared birds.

MANAGEMENT OF LAYING CHICKENS

Most laying pullets are housed in cages and should be moved to these facilities at least 1 wk before egg production begins. Breeders moved from a growing house to

an adult house should also be given at least 1 wk to adjust to their new environment before the stress of egg production begins. Beaks should be retrimmed as necessary, and cull birds removed at the time of rehousing.

Feeders and waterers should be of the proper type, size, and height for the stock and management system. Feeders that are too shallow, too narrow, or lacking a lip or flange on the upper edge may permit excess feed waste. Uneven distribution of waterers or lack of water space results in reduced intake and thus reduced performance.

Artificial Lights: Day length should be increased gradually as the pullets come into egg production and should reach a 14- to 16-hr light period/day at peak production for both market-egg and hatching-egg layers. An intensity of at least 1 foot-candle of light (10 lux) at the feed trough should be provided; this is about equal to one 60-watt light bulb to each 100 sq ft (~9 sq m), hanging 7 ft (2.1 m) above the birds. Production may decrease if day length or light intensity is reduced during the laying period. With cage systems of all types, illumination is more even if smaller wattage bulbs placed closer together are used, rather than large bulbs suspended over the center of each aisle. With

TABLE 16 VACCINATION PROGRAM FOR BROILERS^a

Vaccine	Age	Route	Type
Marek's disease ^b	1 day	SC	Turkey herpesvirus and SB-1 or Rispens strain for high-challenge areas
Newcastle disease	1 day or 14–21 days	Coarse spray Water or coarse spray	B1 B1 or LaSota
Infectious bronchitis	1 day or 14–21 days	Coarse spray Water or coarse spray	Massachusetts Massachusetts
Infectious bursal disease	14–21 days	Water	Intermediate

^a This is an example of a typical vaccination program. Individual programs are highly variable and reflect local conditions, disease prevalence, severity of challenge, and individual preferences.

^b Most USA commercial broiler hatcheries use an in ovo vaccination system for Marek's disease at 17–19 days of embryonation. Infectious bursal disease vaccine (mild strain) may be combined with Marek's disease vaccines. Vectored vaccines in which Marek's and fowlpox vaccines have been safely modified to carry immunizing antigens for laryngotracheitis, Newcastle disease, or infectious bursal disease are also commonly used in ovo or day-old chicks. Connecticut strain is often combined with Massachusetts. Bronchitis vaccine is usually combined with Newcastle. Other bronchitis strains such as Arkansas 99 and Florida 88 are included in some areas. Vaccinations at 14–21 days are optional. A single drinking water application for Newcastle disease/bronchitis is also common.

disease history, medication and vaccination dates, quantity and type of feed given (important in calculating efficiency of feed utilization), and mortality.

Floor Space, Feeding, and Water Requirements:

Eggproduction birds usually spend their entire lives in cages. Although some broiler breeders are similarly housed, most are reared on litter floors or in pens in which as much as two-thirds of the floor is slatted. For egg-strain pullets reared in cages, there is little chance of altering the feeding and watering space available, but periodic checks are necessary to ensure that feed and water are being continuously supplied. With the success of nipple- and cup-waterers and the various types of automatic feeding systems, it becomes more difficult to give specific recommendations for feeding and watering space. Decisions must be made about optimal floor space and feeding and watering requirements based on advice from equipment manufacturers, primary breeders, careful observation, and past experience as to productivity. See TABLE 22 and TABLE 23 for space requirements for egg-strain and meat-strain birds. Environmental housing and various types of ventilation may alter these specifications.

Layers per Cage: Within the guidelines indicated in TABLE 22 and TABLE 23, most colony cages house 5–10 layers. The ideal flock size depends on several factors, including labor and cost, and is best determined by the individual poultry manager or producer.

ORGANIC PRODUCTION PRACTICES

Organic Poultry: According to livestock standards, birds for slaughter designated as organic must be raised under organic management starting no later than the second day of life. Preventive management practices, including the use of vaccines to keep animals healthy, are used; however, antibiotics cannot be used for any reason, and federal regulations prohibit the use of hormones in all poultry. Organic management standards prohibit producers from withholding treatment from a sick or injured animal, but animals treated with a prohibited medication may not be sold as organic. All organically raised animals must have access to the outdoors; they may be temporarily confined only for reasons of health, safety, or to protect soil or water quality.

For a product to be labeled with the “USDA organic” seal, it must comply with

TABLE 7 VACCINATION PROGRAM FOR BROILER BREEDERS^a

Age	Vaccine	Route	Type
1 day	Marek's disease	SC	Turkey herpesvirus

10–12 wk	Laryngotracheitis	Intraocular	Modified live
10–14 wk	<i>Mycoplasma gallisepticum</i> ^b	Intraocular or spray	Mild live strain
or 18 wk		Parenteral	Inactivated
12–14 wk	Newcastle/infectious bronchitis	Water or aerosol	B1 or LaSota/Mass
16–18 wk	Newcastle/infectious bronchitis	Water or aerosol	B1 or LaSota/Mass
Every 60–90 days or 18 wk	Newcastle/infectious bronchitis	Parenteral	Inactivated

^a This is an example of a vaccination program. Individual programs are highly variable and reflect local conditions, disease prevalence, severity of challenge, and individual preferences.

^b The use of *M. gallisepticum* vaccine is regulated or prohibited in some states. SB-1 or MDV301 may be combined with turkey herpesvirus in some areas, or Rispons strain may be used in high-challenge areas. Vaccination for infectious bursal disease, laryngotracheitis, and fowlpox depends on local requirements. Other strains of infectious bronchitis (Connecticut, Arkansas 99, Florida 88, etc) are included in some areas. *M. gallisepticum* and *Haemophilus gallinarum* (coryza) are used only on infected, multiage premises in some areas.

USDA National Organic Standards. Congress passed the Organic Foods Production Act in 1990, and the USDA established national organic standards in 2002. As of 2011, the organic layer flock in the USA was approximately 6.5 million hens, and the average number of organic broilers processed each week was approximately 0.5 million birds. This represents approximately 2.3% of the layer population and 0.3% of the broiler production. In the years from 2001 to 2011, the organic layer flock has grown 400%, and broilers processed as organic has grown 900%. However, it is important to realize that there are years in the past 10 when both layer and broiler organic numbers have shrunk from one year to the next. Growth of these areas is not a straight and predictable line.

The first step toward organic certification for a poultry producer is to select a third-party certifier. The USDA keeps an actively updated list of accredited certification agencies, all of which follow the same USDA National Organic Standards. The producer then submits an application and Organic System Plan (OSP) to the selected certification agency. In livestock production, this plan includes information on the animal source, feeding practices, management practices, health care, recordkeeping, and product labeling. The certifier then reviews the OSP and, if it is deemed adequate, assigns a qualified organic inspector to the livestock facility. The inspector conducts a detailed evaluation of the OSP and the actual farm practices, provides a written exit interview

^a Recommendations are for production areas where the diseases listed are common. In addition, other vaccinations may be advisable if previous experience indicates prevalence of certain diseases in the area. These may include turkey bordetellosis eye drop vaccine at 1 day old and in water or spray at 14 days old, or bacterin; paramyxovirus 3 and influenza A (prevalent hemagglutinin) at 26–28 and 40 wk old; erysipelas—live or killed products might be required for market turkeys, and repeated vaccinations might be required for breeders; and salmonellosis bacterins at 24 and 28 wk old.

^b Recommended age at vaccination is an approximation.

^c ND = Newcastle disease

^d Spray ND vaccines should not be used for birds suffering from respiratory disease; in such cases and at that age, the mild B1-B1 strain vaccine could be used in water. Timing of vaccination depends on maternal antibody levels.

^e DW = drinking water; WW = wing web stab

^f Live fowl cholera vaccines should be used only in healthy flocks.

of findings to the producer, and prepares a report to the certifier. If the farm is found to meet all National Organic Program standards, an organic certificate may be issued. The livestock product must be labeled with information identifying both the producer and certifier (“Certified organic by . . .”). The use of the USDA organic seal on packaging is optional. Organic certification requires annual inspections of the poultry farm.

Animal Production Claims and “Natural” Claims:

The USDA Food Safety and Inspection Service (FSIS) permits the use of animal production claims and the term “natural.” FSIS permits the application of “animal production claims” (ie, truthful statements about the raising of animals from which meat and poultry products are derived) on the labeling of meat and poultry products. For many years,

TABLE 20 VACCINATION PROGRAM FOR DUCK BREEDERS

Age	Vaccine	Route	Type
1 day old	<i>Riemerella anatipestifer</i>	Aerosol	Live vaccine ^a

10 and 20 wk	Duck viral hepatitis	SC	Killed virus vaccine (Type 1)

^a A live, avirulent vaccine consisting of the three major serotypes (1, 2, and 5) of *R anatipestifer*

^b A formalin-inactivated cell suspension of the three major serotypes (1, 2, and 5) of *R anatipestifer*. Bacterins and killed virus vaccines are administered SC in the neck.

^c A modified-live virus vaccine of chick embryo origin.

^d White Pekin breeder ducks normally start egg production at 24 wk of age. Egg production can be accelerated or delayed and breeder vaccination should be completed before the onset of egg production to optimize the passage of parental immunity to the progeny.

animal production claims have served as an alternative to the use of the term “organic” on the labeling of meat and poultry products in the absence of a uniformly accepted definition. Thus, producers may wish to continue the use of animal production claims (eg, “Raised Without Added Hormones,” “Free Range,” “No Antibiotics Ever,” “All Vegetarian Diet”) on meat and poultry labeling. The system FSIS has in place to evaluate the necessary supporting documentation to ensure the accuracy of animal production claims, such as producer affidavits of specific raising protocols or independent third-party programs with audits, will continue to be used whenever these types of claims are made.

The term “natural” may be used when products contain no artificial ingredients and are no more than minimally processed in accordance with FSIS Policy Memo 055. This term may be used in combination with the claim “certified organic by (a certifying entity)” when these requirements are met. The definition of “naturally raised” is being reviewed by the USDA and may result in changes to these definitions.

NUTRITIONAL DEFICIENCIES

A nutritional deficiency may be due to a nutrient being omitted from the diet, adverse interaction between nutrients in otherwise apparently well-fortified diets, or

TABLE 21 VACCINATION PROGRAM FOR COMMERCIAL DUCKLINGS

Age	Vaccine	Route	Type
1 day old	<i>Riemerella anatipestifer</i>	Aerosol	Live vaccine ^a
10–14 days	<i>R anatipestifer</i>	Drinking water	Live vaccine ^a
3 wk	<i>R anatipestifer</i>	SC	Bacterin ^b

^a A live, avirulent vaccine consisting of the three major serotypes (1, 2, and 5) of *R anatipestifer*

^b A formalin-inactivated cell suspension of the three major serotypes (1, 2, and 5) of *R anatipestifer* is recommended for preventive immunization on farms where the disease is endemic or epidemic. An *Escherichia coli* bacterin can also be used where field challenge warrants. Ducklings should not be vaccinated within 21 days of slaughter.

the overriding effect of specific antinutrients. The latter two scenarios are difficult to diagnose, because diet analysis suggests a normal level of the nutrient(s) under investigation. Micronutrients such as vitamins and trace minerals are usually added to diets in the form of stand-alone micro premixes, so it is rare to see classic symptoms of deficiency of individual nutrients—rather, the effect seen is more commonly a compilation of many individual metabolic conditions. In many instances, a correct diagnosis can be made only by obtaining complete information about diet and management, clinical signs in the affected living birds, necropsies, and tissue analyses. Unfortunately, tissue, and especially liver and serum analysis, can be misleading, because relative to the time of initial occurrence of any deficiency, the bird often sequesters nutrients in the liver, and so even with deficient diets, liver assays show erroneously high values. This latter effect is most significant for minerals such as copper.

A diet that, by analysis, appears to contain just enough of one or more nutrients may actually be deficient to some degree in those nutrients. Stress (bacterial, parasitic, or viral infections; high or low temperatures; etc) may either interfere with absorption of a nutrient or increase the quantity required. Thus, a toxin or microorganism, for example, may destroy or render unavailable to the bird a particular nutrient that is present in the diet at apparently adequate levels according to conventional chemical or physical assay procedures.

PROTEIN, AMINO ACID, AND ENERGY DEFICIENCIES

The optimal level of balanced protein intake for growing chicks is ~18%–23% of the diet; for growing poults and gallinaceous upland game birds, ~26%–30%; and for growing ducklings and goslings, ~20%–22%. If the protein and component amino acid content of the diet is below these levels, birds tend to grow more slowly. Even when a diet contains the recommended quantities of protein, optimal growth also requires sufficient quantities and proper balance of all the essential amino acids.

Few specific signs are associated with a deficiency of the various amino acids, except for a peculiar, cup-shaped appearance of the feathers in chickens with arginine deficiency and loss of pigment in some of the wing feathers in bronze turkeys with lysine deficiency. All deficiencies of

essential amino acids result in retarded growth or reduced egg size or egg production. If a diet is deficient in protein or certain amino acids, the bird may initially consume more feed in an attempt to resolve the deficiency. After a few days, this transient increase in feed intake shifts to a situation of reduced feed intake. Consequently, there will be inferior feed efficiency, and the birds are invariably fatter as a consequence of overconsuming energy.

All commercial breeds of poultry have an amazing ability to consume energy to requirement regardless of dietary energy concentration, assuming they can physically eat enough feed in extreme situations. A deficiency of energy can therefore occur only if the diet is so low in energy concentration that the bird physically cannot eat a sufficient quantity of feed to normalize energy intake. With a deficiency of energy, the bird will grow slowly or stop ovulating. As sources of energy, protein and amino acids will be deaminated, and any lipids will undergo β -oxidation. The latter condition can lead to ketosis, which more commonly occurs in mammals, yet the classic signs are similar.

MINERAL DEFICIENCIES

Calcium and Phosphorus Imbalances

A deficiency of either calcium or phosphorus in the diet of young growing birds results in abnormal bone development, even when the diet contains adequate vitamin D₃ (see p 2937). A deficiency of either calcium or phosphorus results in lack of normal skeletal calcification. Rickets is seen mainly in growing birds, whereas calcium deficiency in laying hens results in reduced shell quality and subsequently osteoporosis. This depletion of bone structure causes a disorder commonly referred to as “cage layer fatigue.” When calcium is mobilized from bone to overcome a dietary deficiency, the cortical bone erodes and is unable to support the weight of the hen.

Rickets: Rickets occurs most commonly in young meat birds; the main characteristic is inadequate bone mineralization. Calcium deficiency at the cellular level is the main cause, although feeding a diet deficient or imbalanced in calcium, phosphorus, or vitamin D₃ can also induce this problem. Young broilers and turkey poults can exhibit lameness at ~10–14 days of age. Their bones are rubbery, and the rib cage is flattened and beaded at the attachment of the vertebrae. Rachitic birds exhibit a disorganized cartilage matrix, with an irregular vascular

TABLE 22

MINIMUM SPACE REQUIREMENTS FOR WHITE LEGHORN EGG-STRAIN BIRDS^a

	Age (wk)		
	0–6	7–17	18 onward
CAGES			
Floor area per bird (sq in.)	25	45	60
Straight trough feeder space per bird, not less than (in.)	2	2.5	3

Full fed	3	4	5
Restricted	—	5	—
Waterers			
Birds per fount	100	50	25
Trough space per bird (in.)	1	1	2

^a Requirements for White Leghorns and brown-egg layers are different.

penetration. There is an indication of impaired metabolism of collagen precursors such as hyaluronic acid and desmosine. Rickets is not caused by a failure in the initiation of bone mineralization but rather by impairment of the early maturation of this process. There is often an enlargement of the ends of the long bones, with a widening of the epiphyseal plate. A determination of whether rickets is due to deficiencies of calcium, phosphorus, or vitamin D₃, or to an excess of calcium (which induces a phosphorus deficiency) may require analysis of blood phosphorus levels and investigation of parathyroid activity.

In most field cases of rickets, a deficiency of vitamin D₃ is suspected. This can be due to simple dietary deficiency, inadequate potency of the D₃ supplement, or other factors that reduce the absorption of vitamin D₃. Rickets can best be prevented

by providing adequate levels and potency of vitamin D₃ supplements, and by ensuring that the diet is formulated to ensure optimal utilization of all fat-soluble compounds. Young birds have limited ability to digest saturated fats, and these undigested compounds can complex with calcium to form insoluble soaps, leading to an induced deficiency of calcium. Again, this situation cannot be diagnosed through diet assay for calcium but rather through excreta assay of this mineral. Diets must also provide a correct balance of calcium to available phosphorus. For this reason, ingredients notoriously variable in their content of these minerals, such as animal proteins, should be used with extra caution. In recent years, the use of 25(OH)D₃ has become very popular as a partial replacement for vitamin D₃, with reports of greatly reduced incidence of rickets, especially in poults.

TABLE 23 SPACE REQUIREMENTS FOR MEAT-STRAIN BIRDS

Age	Floor Space ^a	Feeder Space ^b	Cups or Founts ^b (per 1,000 birds)
From day 1	Heated area 5 sq ft brooder/100 chicks	10 trays/1,000 (feed litter and often)	8
From wk 1	1 sq ft/bird	2 in./bird	20
From wk 8	2 sq ft/bird	4 in./bird	30
Mated adults	All litter: 3 sq ft/bird ½ to ⅔ slats: 2¼ sq ft/bird	4 in./bird	30 (60 in hot weather)

^a Welfare programs in broiler production are relatively proscriptive on space requirements and should be appropriately referenced; the below listings are general guidelines.

^b For feeder and drinking trough space, both sides of the trough should be counted. Drinking trough space (all ages) is 1 in. (2.5 cm) per bird but doubled for adults in hot weather.

This metabolite is similar to that naturally produced in the liver of birds in the first step of conversion of vitamin D₃ to 1,25(OH)₂D₃, the active form of the vitamin. The commercial form of 25(OH)D₃ is therefore especially useful if normal liver metabolism is compromised in any way, such as occurs with mycotoxins or other "natural" toxins in the feed that potentially impair liver metabolism.

Tibial Dyschondroplasia (Osteochondrosis): Tibial dyschondroplasia is characterized by an abnormal cartilage mass in the proximal head of the tibiotarsus. It has been seen in all fast-growing types of meat birds but is most common in broiler chickens. Regardless of diet or environmental conditions, fast versus slow growth rate seems to at least double the incidence of tibial dyschondroplasia. Signs can occur early but more usually are not initially seen until 14–25 days of age. Birds are reluctant to move, and when forced to walk, do so with a swaying motion or stiff gait. Tibial dyschondroplasia results from disruption of the normal metaphyseal blood supply in the proximal tibiotarsal growth plate, where the disruption in nutrient supply means the normal process of ossification does not occur. The abnormal cartilage is composed of severely degenerated cells, with cytoplasm and nuclei appearing shrunken. Affected cartilage contains less protein and less DNA.

The exact cause of tibial dyschondroplasia is unknown. Incidence can quickly be altered through genetic selection and is likely affected by a major sex-linked recessive gene. Imbalance of dietary

electrolyte, and particularly high levels of chloride relative to other dietary cations, seem to be a major contributor in many field outbreaks. More tibial dyschondroplasia is also seen when the level of dietary calcium is low relative to that of available phosphorus, or more commonly when diet phosphorus is high relative to calcium. Treatment involves dietary adjustment of the calcium:phosphorus ratio and by achieving a dietary electrolyte balance of ~250 mEq/kg. Dietary changes rarely result in complete recovery. Tibial dyschondroplasia can be prevented by tempering growth rate; however, programs of light or feed restriction must be considered in relation to economic consequences of reduced growth rate. There is evidence that replacement of some of the dietary vitamin D₃ with metabolites such as 1,25(OH)₂D₃ improves chondrocyte differentiation and hence limits occurrence of this skeletal disorder.

Cage Layer Fatigue: High-producing laying hens maintained in cages sometimes show paralysis during and just after the period of peak egg production due to a fracture of the vertebrae that subsequently affects the spinal cord. The fracture is caused by an impaired calcium flux related to the high output of calcium in the eggshell. Layers are capable of early egg production exceeding 95% for at least 6 mo, which places even more pressure on maintenance of adequate calcium flux between the diet, the skeleton, and the oviduct. Because medullary bone reserves become depleted, the bird uses cortical bone as a source of calcium for the eggshell. The condition is rarely seen in floor-housed birds, suggesting

that reduced activity within the cage is a predisposing or associated factor. Affected birds are invariably found on their sides in the back of the cage. At the time of initial paralysis, birds appear healthy and often have a shelled egg in the oviduct and an active ovary. Death occurs from starvation or dehydration, because the birds simply cannot reach feed or water.

Affected birds will recover if moved to the floor. A high incidence of cage layer fatigue can be prevented by ensuring the normal weight-for-age of pullets at sexual maturity and by giving pullets a high-calcium diet (minimum 4% calcium) for at least 7 days before first oviposition. Older caged layers are also susceptible to bone breakage during removal from the cage and transport to processing. It is not known whether cage layer fatigue and bone breakage are related. However, bone strength cannot practically be improved without adverse consequences to other economically important traits such as eggshell quality. Cage layer fatigue is undoubtedly related to high, sustained egg output and associated clutch lengths of 200–230 eggs laid on successive days.

Diets must provide adequate quantities of calcium and phosphorus to prevent deficiencies. However, feeding diets that contain >2.5% calcium during the immature growing period (<16 wk) produces a high incidence of nephritis, visceral gout, calcium urate deposits in the ureters, and sometimes high mortality, especially in the presence of infectious bronchitis virus. Eggshell strength and bone strength can both be improved by feeding ~50% of the dietary calcium supplement in the form of coarse limestone, with the remaining half as fine particle limestone. Offering the coarse supplement permits the birds to satisfy their requirements when they need it most, allowing the coarse material to be retained in the gizzard where the calcium can be absorbed continually and especially at night-time when the bird is not feeding. A readily available calcium and/or calcium phosphate supplement is often effective if started very soon after paralysis is first observed. Although these supplements may be advantageous to afflicted layers, they are not ideal for the regular birds in the flock; therefore, decisions regarding treatment are often influenced by the severity of the condition and the proportion of the flock affected.

Manganese Deficiency

A deficiency of manganese in the diet of immature chickens and turkeys is one of the

potential causes of perosis and chondrodystrophy, and also the production of thin-shelled eggs and poor hatchability in mature birds (*see also* CALCIUM AND PHOSPHORUS IMBALANCES, p 2930).

The most dramatic classic effect of manganese deficiency syndrome is perosis, characterized by enlargement and malformation of the tibiotarsal joint, twisting and bending of the distal end of the tibia and the proximal end of the tarsometatarsus, thickening and shortening of the leg bones, and slippage of the gastrocnemius tendon from its condyles. Increased intakes of calcium and/or phosphorus will aggravate the condition because of reduced absorption of manganese via the action of precipitated calcium phosphate in the intestinal tract. In laying hens, reduced egg production, markedly reduced hatchability, and eggshell thinning are often noted.

A manganese-deficient breeder diet can result in chondrodystrophy in chick embryos. This condition is characterized by shortened, thickened legs and shortened wings. Other signs can include a parrot beak brought about by a disproportionate shortening of the lower mandible, globular contour of the head due to anterior bulging of the skull, edema occurring just above the atlas joint of the neck and extending posteriorly, and protruding of the abdomen due to unassimilated yolk. Growth is also reduced, and development of down and feathers is retarded. A manganese-deficient chick has a characteristic star-gazing posture, because the physiology of the inner ear becomes defective.

Deformities cannot be corrected by feeding more manganese. Effects of manganese deficiency on egg production are fully corrected by feeding a diet that contains at least 30–40 mg of manganese/kg, provided the diet does not contain excess calcium and/or phosphorus. There is an indication of the need for Fe^{2+} ions as well as manganese to correct the deficiency, although most commercial poultry diets contain a surfeit of iron.

Iron and Copper Deficiencies

Deficiencies of both iron and copper can lead to anemia. Iron deficiency causes a severe anemia with a reduction in PCV. In color-feathered strains, there is also loss of pigmentation in the feathers. The birds' requirements for RBC synthesis take precedence over metabolism of feather pigments, although if a fortified diet is introduced, all subsequent feather growth is normal and lines of demarcation on the feathers are part of diagnosis. Iron may

be needed not only for the red feather pigments, which are known to contain iron, but also to function in an enzyme system involved in the pigmentation process. Ochratoxin at 4–8 mcg/g diet also causes an iron deficiency anemia characterized by hypochromic microcytic anemia. Aflatoxin also reduces iron absorption.

Young chicks become lame within 2–4 wk when fed a copper-deficient diet. Bones are fragile and easily broken, the epiphyseal cartilage becomes thickened, and vascular penetration of the thickened cartilage is markedly reduced. These bone lesions resemble the changes noted in birds with a vitamin A deficiency. Copper is required for cartilage formation, and certain antinutrients such as some grain fumigants have been shown to impact skeletal development, likely via interaction with copper metabolism. Copper-deficient chickens may also display ataxia and spastic paralysis.

Copper deficiency in birds, and especially in turkeys, can lead to rupture of the aorta. The biochemical lesion in the copper-deficient aorta is likely related to failure to synthesize desmosine, the cross-link precursor of elastin. The lysine content of copper-deficient elastin is three times that seen in control birds, suggesting failure to incorporate lysine into the desmosine molecule. In field cases of naturally occurring aortic rupture, many birds have <10 ppm copper in the liver, compared with 15–30 ppm normally seen in birds of comparable age. High levels of sulfate ions, molybdenum, and also ascorbic acid can reduce liver copper levels. A high incidence of aortic rupture has been seen in turkeys fed 4-nitrophenylarsonic acid. The problem can be resolved by feeding higher levels of copper, suggesting that products such as 4-nitro may physically complex with copper.

Iodine Deficiency

Iodine deficiency results in a decreased output of thyroxine from the thyroid gland, which in turn stimulates the anterior pituitary to produce and release increased amounts of thyroid stimulating hormone (TSH). This increased production of TSH results in subsequent enlargement of the thyroid gland, usually termed goiter. The enlarged gland results from hypertrophy and hyperplasia of the thyroid follicles, which increases the secretory surface of the follicles.

Lack of thyroid activity or inhibition of the thyroid by administration of thiouracil or thiourea causes hens to cease laying and become obese. It also results in the growth

of abnormally long, lacy feathers. Administration of thyroxine or iodinated casein reverses the effects on egg production, with eggshell quality returning to normal. The iodine content of an egg is markedly influenced by the hen's intake of iodine. Eggs from a breeder fed an iodine-deficient diet will exhibit reduced hatchability and delayed yolk sac absorption. Rapeseed meal and, to a lesser extent, canola meal contain goitrogens that cause thyroid enlargement in young birds. Iodine deficiency in poultry can be avoided by supplementing the feed with as little as 0.5 mg of iodine/kg, although a level of 2–3 mg/kg is more commonly provided to sustain good feathering in fast-growing birds.

Magnesium Deficiency

Natural feed ingredients are rich in magnesium; thus, deficiency is rare and magnesium is never specifically used as a supplement to poultry diets. Newly hatched chicks fed a diet totally devoid of magnesium live only a few days. They grow slowly, are lethargic, and often pant and gasp. When disturbed, they exhibit brief convulsions and become comatose, which is sometimes temporary but often fatal. Mortality is quite high on diets only marginally deficient in magnesium, even though growth of survivors may approach that of control birds.

A magnesium deficiency in laying hens results in a rapid decline in egg production, hypomagnesemia, and a marked withdrawal of magnesium from bones. Egg size, shell weight, and the magnesium content of yolk and shell are decreased. Increasing the dietary calcium of laying hens accentuates these effects. Magnesium seems to play a central role in eggshell formation, although it is not clear whether there is a structural need or whether magnesium simply gets deposited as a cofactor along with calcium.

Magnesium requirements for most classes of chickens seem to be ~500–600 ppm, a level that is usually achieved with contributions by natural feed ingredients.

Potassium, Sodium, and Chloride Deficiencies

Although requirements for potassium, sodium, and chloride have been clearly defined, it is also important to maintain a balance of these and all other electrolytes in the body. Often termed electrolyte balance or acid-base balance, the effects of deficiency of any one element are often a consequence of alteration to this important balance as it affects osmoregulation.

Simple Deficiency: A deficiency of chloride causes ataxia with classic signs of nervousness, often induced by sudden noise or fright. The main sign of hypokalemia is an overall muscle weakness characterized by weak extremities, poor intestinal tone with intestinal distention, cardiac weakness, and weakness and ultimately failure of the respiratory muscles. Hypokalemia is apt to occur during severe stress. Plasma protein is increased, causing the kidney, under the influence of adrenocortical hormone, to discharge potassium into the urine. During adaptation to the stress, blood flow to the muscle gradually improves and the muscle begins uptake of potassium. As liver glycogen is restored, potassium returns to the liver.

Birds fed a diet low in both protein and potassium or that are starving grow slowly but do not show a potassium deficiency. Potassium derived from catabolized tissue protein replaces that lost in the urine. The ratio of potassium to nitrogen in urine is relatively constant and is the same as that found in muscle. Thus, tissue nitrogen and potassium are released together from the catabolized tissue.

A deficiency of sodium leads to a lowering of osmotic pressure and a change in acid-base balance in the body. Cardiac output and blood pressure both decrease, PCV increases, elasticity of subcutaneous tissues decreases, and adrenal function is impaired. This leads to an increase in blood uric acid levels, which can result in shock and death. A less severe sodium deficiency in chicks can result in retarded growth, soft bones, corneal keratinization, impaired food utilization, and a decrease in plasma volume. In layers, reduced egg production, poor growth, and cannibalism may be noted. A number of diseases can result in sodium depletion from the body, such as GI losses from diarrhea or urinary losses due to renal or adrenal damage.

Electrolyte Imbalance: Electrolyte balance is commonly described by the simple formula of $\text{Na} + \text{K} - \text{Cl}$ expressed as mEq/kg of diet. An overall dietary balance of 250–300 mEq/kg is generally considered optimal for normal physiologic function. The buffering systems in the body ensure the maintenance of near normal physiologic pH, preventing electrolyte imbalance. The primary role of electrolytes is in maintenance of body water and ionic balance. Thus, requirements for elements such as sodium, potassium, and chloride cannot be considered individually, because it is the

overall balance that is important. Electrolyte balance, also referred to as acid-base balance, is affected by three factors: the balance and proportion of these electrolytes in the diet, endogenous acid production, and the rate of renal clearance.

In most situations, the body maintains a normal balance between cations and anions in the body such that physiologic pH is maintained. If there is a shift toward acid or base conditions, metabolic processes return the body to a normal pH. Actual electrolyte imbalances are rare, because regulatory mechanisms must sustain optimal cellular pH and osmolarity. Electrolyte balance can therefore more correctly be described as the changes that necessarily occur in the body processes to achieve normal pH. In extreme situations, such modifications in regulatory mechanisms seem to adversely affect other physiologic systems, and they produce or accentuate potentially debilitating conditions.

Electrolyte imbalance causes a number of metabolic disorders in birds, most notably tibial dyschondroplasia and respiratory alkalosis in layers. Tibial dyschondroplasia in young broiler chickens can be affected by the electrolyte balance of the diet. The unusual development of the cartilage plug at the growth plate of the tibia can be induced by a number of factors, although its incidence can be greatly increased by metabolic acidosis induced by feeding products such as NH_4Cl . Tibial dyschondroplasia seems to occur more frequently when the diet contains an excess of sodium relative to potassium, along with very high chloride levels. The latter situation is most easily remedied by substitution of sodium bicarbonate for sodium chloride in the diet.

Overall electrolyte balance is always important but is most critical when chloride or sulfur levels are high. With low dietary chloride levels, there is often little response to the manipulation of electrolyte balance; however, when dietary chloride levels are high, it is critical to make adjustments to the dietary cations to maintain overall balance. Alternatively, chloride levels can be reduced, although chickens have requirements of ~0.12%–0.15% of the diet, and deficiency signs will develop with dietary levels <0.12%. Sodium content of drinking water can have a meaningful impact on total sodium intake of the bird. When drinking water contains >300 ppm of sodium, it may be necessary to reduce sodium levels in the diet. A recent innovation in poultry nutrition that impacts electrolyte balance is the use of phytase enzyme. This commonly used exogenous enzyme supplement is intended to reduce

dependence on supplemental phosphorus, but it has been shown to concomitantly reduce renal excretion of sodium. Diets therefore need less supplemental sodium when they contain phytase enzyme.

Selenium Deficiency

A deficiency of selenium in growing chickens causes exudative diathesis. Early signs of unthriftiness and ruffled feathers usually occur at 3–6 wk of age, depending on the degree of deficiency. The edema results in weeping of the skin, which is often seen on the inner surface of the thighs and wings. The birds bruise easily, and large scabs often form on old bruises. In laying hens, such tissue damage is unusual, but egg production, hatchability, and feed conversion are adversely affected.

The metabolism of selenium is closely linked to that of vitamin E, and signs of deficiency can sometimes be treated with either the mineral or the vitamin. Vitamin E can spare selenium in its role as an antioxidant, and so some selenium-responsive conditions can also be treated by supplemental vitamin E. In most countries, there are limits to the quantity of selenium that can be added to a diet; the upper limit is usually 0.3 ppm.

The commonly used forms are sodium selenite and, more recently, organic selenium chelates. Feeds grown on high-selenium soils are sometimes necessarily used in poultry rations and are good sources of selenium. Fish meal and dried brewer's yeast are also rich in available selenium.

Zinc Deficiency

Zinc requirements and signs of deficiency are influenced by dietary ingredients. In semipurified diets, it is difficult to show a response to zinc levels much above 25–30 mg/kg diet, whereas in practical corn-soybean meal diets, requirement values are increased to 60–80 mg/kg. Such variable zinc needs likely relate to phytic acid content of the diet, because this ligand is a potent zinc chelator. If phytase enzyme is used in diets, the need for supplemental zinc is reduced by up to 10 mg/kg diet.

In young chicks, signs of zinc deficiency include retarded growth, shortening and thickening of leg bones and enlargement of the hock joint, scaling of the skin (especially on the feet), very poor feathering, loss of appetite, and in severe cases, mortality. Although zinc deficiency can reduce egg production in aging hens, the most striking effects are seen in developing embryos.

Chicks hatched from zinc-deficient hens are weak and cannot stand, eat, or drink. They have accelerated respiratory rates and labored breathing. If the chicks are disturbed, the signs are aggravated and the chicks often die. Retarded feathering and frizzled feathers are also found. However, the major defect is grossly impaired skeletal development. Zinc-deficient embryos show micromelia, curvature of the spine, and shortened, fused thoracic and lumbar vertebrae. Toes often are missing and, in extreme cases, the embryos have no lower skeleton or limbs. Some embryos are rumpless, and occasionally the eyes are absent or not developed.

VITAMIN DEFICIENCIES

Vitamin deficiencies are most commonly due to inadvertent omission of a complete vitamin premix from the birds' diet. Multiple signs are therefore seen, although in general, signs of B vitamin deficiencies appear first. Because there are some stores of fat-soluble vitamins in the body, it often takes longer for these deficiencies to affect the bird, and it may take months for vitamin A deficiency to affect adult birds.

Treatment and prevention rely on an adequate dietary supply, usually microencapsulated in gelatin or starch along with an antioxidant. Vitamin destruction in feeds is a factor of time, temperature, and humidity. For most feeds, efficacy of vitamins is little affected over 2-mo storage within mixed feed.

Vitamin A Deficiency

Depending on liver stores, adult birds could be fed a vitamin A-deficient diet for 2–5 mo before signs of deficiency develop. Eventually, birds become emaciated and weak with ruffled feathers. Egg production drops markedly, hatchability decreases, and embryonic mortality increases. As egg production declines, there will likely be only small follicles in the ovary, some of which show signs of hemorrhage. A watery discharge from the eyes may also be noted. As the deficiency continues, milky white, cheesy material accumulates in the eyes, making it impossible for birds to see (xerophthalmia). The eye, in many cases, may be destroyed.

The first lesion usually noted in adult birds is in the mucous glands of the upper alimentary tract. The normal epithelium is replaced by a stratified squamous, keratinized layer. This blocks the ducts of the mucous glands, resulting in necrotic

secretions. Small, white pustules may be found in the nasal passages, mouth, esophagus, and pharynx, and these may extend into the crop. Breakdown of the mucous membrane usually allows pathogenic microorganisms to invade these tissues and cause secondary infections.

Depending on the quantity of vitamin A passed on from the breeder hen, day-old chicks reared on a vitamin A-deficient diet may show signs within 7 days. However, chicks with a good reserve of maternal vitamin A may not show signs of a deficiency for up to 7 wk. Gross signs in chicks include anorexia, growth retardation, drowsiness, weakness, incoordination, emaciation, and ruffled feathers. If the deficiency is severe, the chicks may become ataxic, which is also seen with vitamin E deficiency (*see below*). The yellow pigment in the shanks and beaks is usually lost, and the comb and wattles are pale. A cheesy material may be noted in the eyes, but xerophthalmia is seldom seen because chicks usually die before the eyes become affected. Secondary infection may play a role in many of the deaths noted with acute vitamin A deficiency.

Young chicks with chronic vitamin A deficiency may also develop pustules in the mucous membrane of the esophagus that usually affect the respiratory tract. Kidneys may be pale and the tubules distended because of uric acid deposits, and in extreme cases, the ureters may be plugged with urates. Blood levels of uric acid can rise from a normal level of ~5 mg to as high as 40 mg/100 mL. Vitamin A deficiency does not interfere with uric acid metabolism but does prevent normal excretion of uric acid from the kidney. Histologic findings include atrophy of the cytoplasm and a loss of the cilia in the columnar, ciliated epithelium.

Although vitamin A-deficient chicks can be ataxic, similar to those with vitamin E deficiency, no gross lesions are found in the brain of vitamin A-deficient chicks as compared with degeneration of the Purkinje cells in the cerebellum of vitamin E-deficient chicks (*see below*). The livers of ataxic vitamin A-deficient chicks contain little or no vitamin A.

Because stabilized vitamin A supplements are almost universally used in poultry diets, it is unlikely that a deficiency will be encountered. However, if a deficiency does develop because of either inadvertent omission of the vitamin A supplement or inadequate feed preparation, up to 2 times the normally recommended level, should be fed for ~2 wk. Vitamin A can be administered through the drinking water, and such

treatment usually results in faster recovery than supplementation via the feed.

Vitamin D₃ Deficiency

Vitamin D₃ is required for the normal absorption and metabolism of calcium and phosphorus. A deficiency can result in rickets in young growing chickens or in osteoporosis and/or poor eggshell quality in laying hens, even though the diet may be well supplied with calcium and phosphorus. Abnormal skeletal development is discussed under calcium and phosphorus imbalances (*see p 2930*) and manganese deficiency (*see p 2933*).

Laying hens fed a vitamin D₃-deficient diet show loss of egg production within 2–3 wk, and depending on the degree of deficiency, shell quality deteriorates almost instantly. Using a corn-soybean meal diet with no supplemental vitamin D₃, shell weight decreases dramatically by ~150 mg/day throughout the first 7 days of deficiency. The less obvious decline in shell quality with suboptimal, rather than deficient, supplements is more difficult to diagnose, especially because it is very difficult to assay vitamin D₃ in complete feeds.

There is a significant increase in plasma 1,25(OH)₂D₃ of birds producing good versus poor eggshells. Feeding purified 1,25(OH)₂D₃ improves the shell quality of these inferior layers, suggesting a potential inherent problem with metabolism of cholecalciferol.

Retarded growth and severe leg weakness are the first signs noted when chicks are deficient in vitamin D₃. Beaks and claws become soft and pliable. Chicks may have trouble walking and will take a few steps before squatting on their hocks. While resting, they often sway from side to side, suggesting loss of equilibrium. Feathering is usually poor, and an abnormal banding of feathers may be seen in colored breeds. With chronic vitamin D₃ deficiency, marked skeletal disorders are noted. The spinal column may bend downward and the sternum may deviate to one side. These structural changes reduce the size of the thorax, with subsequent crowding of the internal organs, especially the air sacs. A characteristic finding in chicks is a beading of the ribs at the junction of the spinal column along with a downward and posterior bending. Poor calcification can also be seen at the epiphysis of the tibia and femur. By immersing the split bone in a silver nitrate solution and allowing it to stand under incandescent light for a few minutes, the calcified areas are easily

distinguished from the areas of cartilage. Adding synthetic $1,25(\text{OH})_2\text{D}_3$ to the diet of susceptible chicks reduces the incidence of this condition. Although response is variable, results suggest that some leg abnormalities may be a consequence of inefficient metabolism of cholecalciferol.

In laying hens, signs of gross pathology are usually confined to the bones and parathyroid glands. Bones are soft and easily broken, and the ribs may become beaded. The ribs may also show spontaneous fractures in the sternovertebral region. Histologic examination shows decreased calcification in the long bones, with excess of osteoid tissue and parathyroid enlargement.

Dry, stabilized forms of vitamin D_3 are recommended to treat deficiencies. In cases of severe mycotoxicosis, a water-miscible form of vitamin D_3 is administered in the drinking water to provide the amount normally supplied in the diet. In cases of impaired liver function, metabolites of vitamin D are the usual choice for treatment.

Vitamin E Deficiency

The three main disorders seen in chicks deficient in vitamin E are encephalomalacia, exudative diathesis, and muscular dystrophy. The occurrence of these conditions depends on various other dietary and environmental factors.

Encephalomalacia is seen in commercial flocks if diets are very low in vitamin E, if an antioxidant is either omitted or is not present in sufficient quantities, or if the diet contains a reasonably high level of an unstable and unsaturated fat. For exudative diathesis to occur, the diet must be deficient in both vitamin E and selenium. Signs of muscular dystrophy are rare in chicks, because the diet must be deficient in both sulfur amino acids and vitamin E. Because the sulfur amino acids are necessary for growth, a deficiency severe enough to induce muscular dystrophy is unlikely to occur under commercial conditions. Signs of exudative diathesis and muscular dystrophy can be reversed in chicks by supplementing the diet with liberal amounts of vitamin E, assuming the deficiency is not too advanced. Encephalomalacia may respond to vitamin E supplementation, depending on the extent of the damage to the cerebellum.

The classic sign of encephalomalacia is ataxia. The results from hemorrhage and edema within the granular layers of the cerebellum, with pyknosis and eventual

disappearance of the Purkinje cells and separation of the granular layers of the cerebellar folia. Because of its inherently low level of vitamin E, the cerebellum is particularly susceptible to lipid peroxidation. In prevention of encephalomalacia, vitamin E functions as a biologic antioxidant. The quantitative need for vitamin E for this function depends on the amount of linoleic acid and polyunsaturated fatty acids in the diet. Over prolonged periods, antioxidants have been shown to prevent encephalomalacia in chicks when added to diets with very low levels of vitamin E or in chicks fed vitamin E-depleted purified diets. Chicks hatched from breeders that are given additional dietary vitamin E seem less susceptible to lipid peroxidation in the brain. The fact that antioxidants can help prevent encephalomalacia, but fail to prevent exudative diathesis or muscular dystrophy in chicks, strongly suggests that vitamin E is acting as an antioxidant in this situation. Exudative diathesis results in a severe edema caused by a marked increase in capillary permeability. Electrophoretic patterns of the blood show a decrease in albumin levels, whereas exudative fluids contained a protein pattern similar to that of normal blood plasma.

Vitamin E deficiency accompanied by sulfur amino acid deficiency results in severe muscular dystrophy in chicks by ~4 wk of age. This condition is characterized by degeneration of the muscle fibers, usually in the breast but sometimes also in the leg muscles. Histologic examination shows Zenker's degeneration, with perivascular infiltration and marked accumulation of infiltrated eosinophils, lymphocytes, and histocytes. Accumulation of these cells in dystrophic tissue results in an increase in lysosomal enzymes, which appear to function in the breakdown and removal of the products of dystrophic degeneration. Initial studies involving the effects of dietary vitamin E on muscular dystrophy show that the addition of selenium at 1–5 mg/kg diet reduced the incidence of muscular dystrophy in chicks receiving a vitamin E-deficient diet that was also low in methionine and cysteine, but did not completely prevent the disease. However, selenium was completely effective in preventing muscular dystrophy in chicks when the diet contained a low level of vitamin E, which alone had been shown to have no effect on the disease. Throughout the past few years, the incidence of "muscular dystrophy-type" lesions in the breast muscle of older (>35 day) broilers

has increased. Characteristic parallel white striations on the muscle are similar to those seen in chicks with muscular dystrophy, yet on analysis the diet of these birds seems adequate in vitamin E as well as selenium.

Studies with chicks on the interrelationships between antioxidants, linoleic acid, selenium, and sulfur amino acids have shown that selenium and vitamin E play supportive roles in several processes, one of which involves cysteine metabolism and its role in prevention of muscular dystrophy in chickens. Glutathione peroxidase is soluble and located in the aqueous portions of the cell, whereas vitamin E is located mainly in the hydrophobic environments of membranes and in adipose tissue and other lipid storage cells. The overlapping manner in which vitamin E and selenium function in the cellular antioxidant system suggest that they spare one another in prevention of deficiency signs.

Only stabilized fat should be used in feeds. Adequate levels of stabilized vitamin E should be used in conjunction with a commercial antioxidant and at least 0.3 ppm selenium. Signs of exudative diathesis and muscular dystrophy due to vitamin E deficiency can be reversed if treatment is begun early by administering vitamin E through the feed or drinking water. Oral administration of a single dose of vitamin E (300 IU per bird) usually causes remission.

Vitamin K Deficiency

Impairment of blood coagulation is the major clinical sign of vitamin K deficiency. With a severe deficiency, subcutaneous and internal hemorrhages can prove fatal. Vitamin K deficiency results in a reduction in prothrombin content of the blood, and in the young chick, plasma levels are as low as 2% of normal. Because the prothrombin content of newly hatched chicks is only ~40% that of adult birds, young chicks are readily affected by a vitamin K-deficient diet. A carryover of vitamin K from the hen to eggs, and subsequently to hatched chicks, has been demonstrated, so breeder diets should be well fortified. Hemorrhagic syndrome in day-old chicks has been attributed to a deficiency of vitamin K in the diet of the breeder hens. Gross deficiency of vitamin K results in such prolonged blood clotting that severely deficient chicks may bleed to death from a slight bruise or other injury. Borderline deficiencies often cause small hemorrhagic blemishes. Hemorrhages may appear on the breast, legs, wings, in the abdominal cavity, and on the surface of the

intestine. Chicks are anemic, which may be due in part to loss of blood but also to development of hypoplastic bone marrow. Although blood-clotting time is a reasonable measure of the degree of vitamin K deficiency, a more accurate measure is obtained by determining the prothrombin time. Prothrombin times in severely deficient chicks may be extended from a normal of 17–20 sec to 5–6 min or longer. No major heart lesions are seen in vitamin K-deficient chicks such as those that occur in pigs.

A vitamin K deficiency in poultry may be related to low dietary levels of the vitamin, low levels in the maternal diet, lack of intestinal synthesis, extent of coprophagy, or the presence of sulfur drugs and other feed additives in the diet. Chicks with coccidiosis can have severe damage to their intestinal wall and can bleed excessively. Antimicrobial agents can suppress intestinal synthesis of vitamin K, rendering the bird completely dependent on the diet for its supply of the vitamin. Synthesis of vitamin K does occur in the bacteria resident in the bird's digestive tract; however, such vitamin K remains inside the bacterial cell, so the only benefit to the bird arises from the bacterial cell digestion or via coprophagy.

The inclusion of menadione at 1–4 mg/ton of feed is an effective and common practice to prevent vitamin K deficiency. If signs of deficiency are seen, the level should be doubled. A number of stress factors (eg, coccidiosis and other intestinal parasitic diseases) increase the requirements for vitamin K. Dicumarol, sulfaquinoxaline, and warfarin are antimetabolites of vitamin K.

Vitamin B₁₂ Deficiency

Vitamin B₁₂ is an essential part of several enzyme systems, with most reactions involving the transfer or synthesis of methyl groups. Although the most important function of vitamin B₁₂ is in the metabolism of nucleic acids and proteins, it also functions in carbohydrate and fat metabolism.

In growing chickens, a deficiency of vitamin B₁₂ results in reduced weight gain and feed intake, along with poor feathering and nervous disorders. Although deficiency may lead to perosis, this is probably a secondary effect due to a dietary deficiency of methionine or choline as sources of methyl groups. Vitamin B₁₂ may alleviate perosis because of its effect on the synthesis of methyl groups. Other signs reported in poultry are anemia, gizzard erosion, and fatty infiltration of the heart, liver, and kidneys. Laying hens initially appear to be

able to maintain body weight and egg production; however, egg size is reduced. In breeders, hatchability can be markedly reduced, although several weeks may be needed for signs of deficiency to appear. Changes noted in embryos from B₁₂-deficient breeders include a general hemorrhagic condition, fatty liver, fewer myelinated fibers in the spinal cord, and high incidence of mid-term embryo deaths.

Deficiency of vitamin B₁₂ is highly unlikely, especially for birds grown on litter or where animal-based ingredients are used. Treatment involves feeding up to 20 mcg/g feed for 1–2 wk.

Choline Deficiency

In addition to poor growth, the classic sign of choline deficiency in chicks and poults is perosis. Perosis is first characterized by pinpoint hemorrhages and a slight puffiness about the hock joint, followed by an apparent flattening of the tibiotarsal joint caused by a rotation of the metatarsus. The metatarsus continues to twist and may become bent or bowed so that it is out of alignment with the tibia. When this condition exists, the leg cannot adequately support the weight of the bird. The articular cartilage is displaced, and the Achilles tendon slips from its condyles. Perosis is not a specific deficiency sign; it appears with several nutrient deficiencies.

Although choline deficiency readily develops in chicks fed diets low in choline, a deficiency in laying hens is not easily produced. Eggs contain ~12–13 mg of choline/g of dried whole egg. A large egg contains ~170 mg of choline, found almost entirely in the phospholipids. Thus, there appears to be a considerable need for choline to produce an egg. In spite of this, producing a marked choline deficiency in laying hens has been difficult, even when highly purified diets essentially devoid of choline are provided for a prolonged period. Under these conditions, the choline content of eggs is not reduced, suggesting possible intestinal synthesis by the bird.

Diets that contain appreciable quantities of soybean meal, wheat bran, and wheat shorts are unlikely to be deficient in choline. Soybean meal is a good source of choline, and wheat byproducts are good sources of betaine, which can perform the methyl-donor function of choline. Other good sources of choline are distiller's grains, fishmeal, liver meal, meat meals, distiller's solubles, and yeast. A number of commercial choline supplements are available, and supplemental choline is routinely used in most poultry feeds.

Niacin (Nicotinic Acid) Deficiency

There is considerable evidence that poultry, and even chick and turkey embryos, can synthesize niacin but at a rate too slow for optimal growth. It has been claimed that a marked deficiency of niacin cannot occur in chickens unless there is a concomitant deficiency of the amino acid tryptophan, which is a niacin precursor.

Niacin deficiency is characterized by severe disorders in the skin and digestive organs. The first signs are usually loss of appetite, retarded growth, general weakness, and diarrhea. Deficiency produces enlargement of the tibiotarsal joint, valgus-varus bowing of the legs, poor feathering, and dermatitis on the head and feet.

Niacin deficiency in chicks can also result in "black tongue." At ~2 wk of age, the tongue, oral cavity, and esophagus become distinctly inflamed. In the niacin-deficient hen, weight loss, reduced egg production, and a marked decrease in hatchability can result. Turkeys, ducks, pheasants, and goslings are much more severely affected by niacin deficiency than are chickens. Their apparently higher requirements are likely related to their less efficient conversion of tryptophan to niacin. Ducks and turkeys with a niacin deficiency show a severe bowing of the legs and an enlargement of the hock joint. The main difference between the leg seen in niacin deficiency and perosis as seen in manganese and choline deficiency is that with niacin deficiency the Achilles tendon seldom slips from its condyles.

Niacin deficiency in chickens may be prevented by feeding a diet that contains niacin at ≥30 mg/kg; however, many nutritionists recommend 2–2.5 times as much. An allowance of 55–70 mg/kg of feed appears to be satisfactory for ducks, geese, and turkeys. Ample niacin should be provided in poultry diets so as to spare the utilization of tryptophan.

Pantothenic Acid Deficiency

Pantothenic acid is the prosthetic group within coenzyme A, an important coenzyme involved in many reversible acetylation reactions in carbohydrate, fat, and amino acid metabolism. Signs of deficiency therefore relate to general avian metabolism.

The major lesions of pantothenic acid deficiency involve the nervous system, the adrenal cortex, and the skin. Deficiency may result in reduced egg production; however, a marked drop in hatchability is usually noted before this event. Embryos from hens with pantothenic acid deficiency can have subcutaneous hemorrhages and severe

edema, with most mortality showing up during the later part of the incubation period. In chicks, the first signs are reduced growth and feed consumption, poor feathering with feathers becoming ruffled and brittle, and a rapidly developing dermatitis. The corners of the beak and the area below the beak are usually the worst affected regions for dermatitis, but the condition is also noted on the feet. In severe cases, the skin of the feet may cornify, and wart-like lumps occur on the balls of the feet. The foot problem often leads to bacterial infection.

Liver concentration of pantothenic acid is reduced during a deficiency, with the liver becoming atrophied, with a faint dirty yellow color developing. Nerve fibers of the spinal cord may show myelin degeneration. Pantothenic acid-deficient chicks show lymphoid cell necrosis in the bursa of Fabricius and thymus, together with lymphocytic paucity in the spleen. The foot condition in chicks and the poor feathering are difficult to differentiate from signs of a biotin deficiency. In a pantothenic acid deficiency, dermatitis of the feet is usually noted first on the toes; in contrast, a biotin deficiency primarily affects the foot pads and is usually more severe. Ducks do not show the usual signs noted for chickens and turkeys, except for retarded growth, but mortality can be quite high.

Most poultry diets contain supplements of calcium pantothenate. Periodically, growing chickens fed practical diets develop a scaly condition of the skin, the exact cause of which is not known. Treatment with both calcium pantothenate (2 g) and riboflavin (0.5 g) in the drinking water (50 gal [190 L]) for a few days has been successful in some instances. Diets usually contain supplemental pantothenic acid at 12 mg/kg.

Riboflavin Deficiency

Many tissues may be affected by riboflavin deficiency, although the epithelium and the myelin sheaths of some of the main nerves are major targets. Changes in the sciatic nerves produce "curled-toe" paralysis in growing chickens. Egg production is affected, and riboflavin-deficient eggs do not hatch. When the diet is inadvertently devoid of the entire spectrum of vitamins, it is signs of riboflavin deficiency that first appear. When chicks are fed a diet deficient in riboflavin, their appetite is fairly good but they grow slowly, become weak and emaciated, and develop diarrhea between the first and second weeks. Deficient chicks are reluctant to move unless forced and

then frequently walk on their hocks with the aid of their wings. The leg muscles are atrophied and flabby, and the skin is dry and harsh. In advanced stages of deficiency, the chicks lie prostrate with their legs extended, sometimes in opposite directions. The characteristic sign of riboflavin deficiency is a marked enlargement of the sciatic and brachial nerve sheaths; sciatic nerves usually show the most pronounced effects. Histologic examination of the affected nerves shows degenerative changes in the myelin sheaths that, when severe, pinch the nerve. This produces a permanent stimulus, which causes the curled-toe paralysis.

Signs of riboflavin deficiency in hens are decreased egg production, increased embryonic mortality, and an increase in size and fat content of the liver. Hatchability declines within 2 wk when hens are fed a riboflavin-deficient diet but returns to near normal when riboflavin is restored. Affected embryos are dwarfed and show characteristically defective "clubbed" down. The nervous system of these embryos shows degenerative changes much like those described in riboflavin-deficient chicks. Clubbed down is periodically seen in cases of poor hatchability, when the "reject" chicks or dead embryos show this condition, even though the breeder diet is apparently adequate in riboflavin. Anecdotal evidence suggests greater occurrence of this clubbed-down condition in farms that select "floor-eggs" for incubation.

Signs of riboflavin deficiency first appear at 10 days of incubation, when embryos become hypoglycemic and accumulate intermediates of fatty acid oxidation. Although flavin-dependent enzymes are depressed with riboflavin deficiency, the main effect seems to be impaired fatty acid oxidation, which is a critical function in the developing embryo. An autosomal recessive trait blocks the formation of the riboflavin-binding protein needed for transport of riboflavin to the egg. Although the adults appear normal, their eggs fail to hatch regardless of dietary riboflavin content. As eggs become deficient in riboflavin, the egg albumen loses its characteristic yellow color. In fact, albumen color score has been used to assess riboflavin status of birds.

Chicks receiving diets only partially deficient in riboflavin may recover spontaneously, indicating that the requirement rapidly decreases with age. A 100-mcg dose should be sufficient for treatment of riboflavin-deficient chicks, followed by incorporation of an adequate level in the diet. However, when the curled-toe deformity is longstanding, irreparable damage occurs in the sciatic

nerve, and the administration of riboflavin is no longer curative.

Most diets contain up to 10 mg of riboflavin/kg. Treatment can be given as two sequential daily 100-mcg doses for chicks or poults, followed by an adequate amount of riboflavin in feed.

Folic Acid (Folacin) Deficiency

A folacin deficiency results in a macrocytic (megaloblastic) anemia and leukopenia. Tissues with a rapid turnover, such as epithelial linings, GI tract, epidermis, and bone marrow, as well as cell growth and tissue regeneration, are principally affected.

Poultry seem more susceptible to folacin deficiency than other farm animals.

Deficiency results in poor feathering, slow growth, an anemic appearance, and sometimes perosis. As anemia develops, the comb becomes a waxy-white color, and pale mucous membranes in the mouth are noted. Increased erythrocyte phosphoribosylpyrophosphate concentration can be used as a diagnostic tool in folacin-deficient chicks. There may also be damage to liver parenchyma and depleted glycogen reserves. Although turkey poultens show some of the same signs as chickens, mortality is usually higher and the birds develop a spastic type of cervical paralysis that results in the neck becoming stiff and extended.

The abnormal feather condition in chickens leads to weak and brittle shafts, and depigmentation develops in colored feathers. Although a folacin deficiency can result in reduced egg production, the main sign noted with breeders is a marked decrease in hatchability associated with an increase in embryonic mortality, usually during the last few days of incubation. Embryos have deformed beaks and bending of the tibiotarsus. Birds may exhibit perosis, but the lesions seen differ histologically from those that develop due to choline or manganese deficiency. Abnormal structure of the hyaline cartilage and retardation of ossification are noted with folacin deficiency. Increasing the protein content of the diet has been shown to increase the severity of perosis in chicks receiving diets low in folic acid, because there is an increased folacin demand for uric acid synthesis.

Signs of folic acid deficiency in poultry can be prevented by ensuring diets contain supplements of up to 1 mg/kg.

Biotin Deficiency

Biotin deficiency results in dermatitis of the feet and the skin around the beak and eyes

similar to that described for pantothenic acid deficiency (*see* p 2940). Perosis and footpad dermatitis are also characteristic signs. Although signs of classic biotin deficiency are rare, occurrence of fatty liver and kidney syndrome (FLKS) is important to commercial poultry producers. FLKS was first described in Denmark in 1958 but was not a major concern until the late 1960s, when the condition became more prevalent and especially so in Europe and Australia. Chicks ~3 wk old become lethargic and unable to stand, then die within hours. Mortality is usually quite low at 1%–2% but can reach 20%–30%. Postmortem examination reveals pale liver and kidney with accumulation of fat.

The condition as described in the 1960s was usually confined to wheat-fed birds and was most problematic in low-fat, high-energy diets. High vitamin supplementation in general corrected the problem, and biotin was isolated as the causative agent. It is now known that biotin in wheat has exceptionally low availability. The trigger of high-energy diets led to investigation of biotin in carbohydrate metabolism. Chicks with FLKS are invariably hypoglycemic, emphasizing the importance of biotin in two key enzymes, namely pyruvate carboxylase and acetyl Co-A carboxylase. Acetyl Co-A carboxylase appears to preferentially sequester biotin, such that with low biotin availability and need for high *de novo* fat synthesis (high-energy, low-fat diet), pyruvate carboxylase activity is severely compromised. Even with this imbalance, birds are able to grow. However, with a concurrent deprivation in feed intake or increased demand for glucose, hypoglycemia develops, leading to adipose catabolism and the characteristic accumulation of fat in both liver and kidneys. Birds with FLKS rarely show signs of classic biotin deficiency.

Plasma biotin levels <100 ng/100 mL have been reported as a sign of deficiency. However, recent evidence suggests that plasma biotin levels are quite insensitive to the birds' biotin status, and that biotin levels in the liver or kidneys are more useful indicators. Plasma pyruvic carboxylase is positively correlated with dietary biotin concentration, and levels plateau much later than does the growth response to supplemental biotin.

Embryos are also sensitive to biotin status. Congenital perosis, ataxia, and characteristic skeletal deformities may be seen in embryos and newly hatched chicks when hens are fed a deficient diet. Embryonic deformities include a shortened tibiotarsus that is bent posteriorly, a much

shortened tarsometatarsus, shortening of the bones of the wing and skull, and shortening and bending of the anterior end of the scapula. Syndactyly, which is an extensive webbing between the third and fourth toes, is seen in biotin-deficient embryos. Such embryos are chondrodystrophic and characterized by reduced size, parrot beak, crooked tibia, and shortened or twisted tarsometatarsus.

A number of factors increase biotin requirements, including oxidative rancidity of any feed fat, competition by intestinal microorganisms, and lack of carryover into the newly hatched chick or poult. It is good practice to add 150 mg biotin/tonne of feed, especially when significant amounts of wheat or wheat byproducts are used in the diet.

Pyridoxine (Vitamin B₆) Deficiency

A vitamin B₆ deficiency causes retarded growth, dermatitis, and anemia. Because a major role of the vitamin is in protein metabolism, deficiency can result in reduced nitrogen retention. Dietary protein is not well utilized, and thus nitrogen excretion increases. Increased iron levels and decreased copper levels are noted in the serum, and iron utilization appears to be markedly decreased. The resulting anemia is likely due to a disturbance in the synthesis of protoporphyrins. Anemia is often noted in ducks but is seldom seen in chickens and turkeys. Young chicks may show nervous movements of the legs when walking and often undergo spasmodic convulsions, leading to death. During convulsions, the chicks may run about aimlessly, flapping their wings and falling with jerking motions. The greater intensity of activity, resulting from vitamin B₆ deficiency, distinguishes these signs from those of encephalomalacia. Gizzard erosion has been noted in vitamin B₆-deficient chicks. It can be prevented by inclusion of 1% taurocholic acid in the diet, leading to the speculation that pyridoxine is involved in taurine synthesis and is important for gizzard integrity. In pyridoxine deficiency, collagen maturation is incomplete, suggesting that this vitamin is essential for integrity of the connective tissue matrix. A chronic deficiency can result in perosis, with one leg usually being crippled and one or both middle toes bent inward at the first joint.

In adult birds, pyridoxine deficiency results in reduced appetite, leading to reduced egg production and a decline in

hatchability. Severe deficiency can cause rapid involution of the ovary, oviduct, comb, and wattles, and of the testis in cockerels. Feed consumption in vitamin B₆-deficient hens and cockerels declines sharply. Although a partial molt is seen in some hens, normal egg production returns within 2 wk after provision of a normal dietary level of pyridoxine.

Deficiency can be prevented by adding pyridoxine at 3–4 mg/kg feed.

Thiamine Deficiency

Polyneuritis in birds represents the later stages of a thiamine deficiency, probably caused by buildup of the intermediates of carbohydrate metabolism. Because the brain's immediate source of energy results from the degradation of glucose, it depends on biochemical reactions involving thiamine. In the initial stages of deficiency, lethargy and head tremors may be noted. A marked decrease in appetite is seen in birds fed a thiamine-deficient diet. Poultry are also susceptible to neuromuscular problems, resulting in impaired digestion, general weakness, star-gazing, and frequent convulsions.

Polyneuritis may be seen in mature birds ~3 wk after they are fed a thiamine-deficient diet. As the deficiency progresses, birds may sit on flexed legs and draw back their heads in a star-gazing position. Retraction of the head is due to paralysis of the anterior neck muscles. Soon after this stage, chickens lose the ability to stand or sit upright and topple to the floor, where they may lie with heads still retracted. Thiamine deficiency may also lead to a decrease in body temperature and respiratory rate. Testicular degeneration may be noted, and the heart may show slight atrophy. Birds consuming a thiamine-deficient diet soon show severe anorexia. They lose all interest in feed and will not resume eating unless given thiamine. If a severe deficiency has developed, thiamine must be force-fed or injected to induce the chickens to resume eating.

Thiamine deficiency is most common when poorly processed fish meals are used, because they contain thiaminase enzyme. In such situations, adding extra thiamine may be ineffective. There is no good evidence suggesting that, unlike in some mammalian species, certain *Fusarium* mycotoxins can increase the need for supplemental thiamine. In otherwise adequate diets, deficiency is prevented by supplements of thiamine up to 4 mg/kg.

TOXICOLOGY INTRODUCTION

For a discussion of common poisonings in poultry, *see* p 2859.

Veterinary toxicology involves the evaluation of toxicosis and deficiencies, identification and characterization of toxins and determination of their fate in the body, and treatment of toxicosis. Toxicology has been receiving even more attention in the general public with the widespread interest in crime scene investigator (CSI) television shows. The recent worldwide melanine contamination in pet and swine feed, pet jerky treats causing illness and death, and concerns with use of β -agonists in food animals demonstrates the relevancy of veterinary toxicology to current animal health and food safety. Veterinary toxicology can be challenging because of the low frequency of cases observed in a practice setting. When a toxicosis occurs, it often involves a large number of animals and may also involve litigation. A current veterinary toxicology reference book is helpful to ensure the correct samples are obtained and submitted for diagnosis.

A toxic agent is referred to as a toxicant or poison. The term **toxin** refers to a poison produced by a biologic source (eg, venoms, plant toxins); the redundant term biotoxin is occasionally used. **Toxicosis**, **poisoning**, and **intoxication** are synonymous terms for the disease produced by a toxicant. **Toxicity** (sometimes incorrectly used instead of poisoning) refers to the amount of a toxicant necessary to produce a detrimental effect.

Acute toxicosis refers to effects during the first 24-hr period. Effects produced by prolonged exposure (≥ 3 mo) are referred to as **chronic toxicosis**. Terms such as subacute and subchronic are used to cover the large gap between acute and chronic.

All toxic effects are dose dependent. A dose may cause undetectable, therapeutic, toxic, or lethal effects. A dose is expressed as the amount of compound per unit of body weight, and toxicant concentration as part per million or part per billion. These quantitative expressions are also used for feedstuffs, water, and air, as well as for tissue levels.

LD₅₀ is the dose that is lethal to 50% of a test sample. It is an estimator of lethality and the most common expression used to rate the potency of toxicants. Other terms used for prediction of illness or lethality include no observed effect level (NOEL), maximum nontoxic dose (MNTD), and maximum tolerated dose or minimum toxic dose (MTD).

ABSORPTION, DISTRIBUTION, METABOLISM, AND EXCRETION

The basis of toxicology involves the absorption, distribution, metabolism, and excretion (ADME) of a toxicant. Knowledge of these processes is important to evaluate risk of exposure to toxins. (See also

DISPOSITION AND FATE OF DRUGS, p 2492.)

Absorption: Absorption may occur through the alimentary tract, skin, lungs, via the eye, mammary gland, or uterus, as well as from sites of injection. Toxic effects may be local, but the toxicant must be dissolved and absorbed to some extent to affect the cell. Solubility is the primary factor affecting absorption. Insoluble salts and ionized compounds are poorly absorbed, whereas lipid-soluble substances are generally readily absorbed, even through intact skin. For example, barium is toxic, but barium sulfate can be used for intestinal contrast radiography because of low absorption.

Distribution: Distribution or translocation of a toxicant is via the bloodstream to reactive sites, including storage depots. The liver receives the portal circulation and is the organ most commonly involved with intoxication (and detoxification). The selective deposit of foreign chemicals in various tissues depends on receptor sites. Ease of chemical distribution depends largely on its water solubility. Polar or aqueous-soluble agents tend to be excreted by the kidneys; lipid-soluble chemicals are more likely to be excreted via the bile and accumulate in fat depots. The highest concentration of a toxin within an animal is not necessarily found in the organ or tissue on which it exerts its maximal effect (the target organ). Lead may be found in highest concentrations in bone, which is neither a site for toxic effects nor a reliable tissue for toxicologic interpretation. Knowledge of the translocation characteristics of toxicants is necessary for proper selection of organs for analysis.

Metabolism: Metabolism or biotransformation of toxicants by the body is an "attempt to detoxify." In some instances,

metabolized xenobiotic agents are more toxic than the original compound. This is referred to as lethal synthesis. Metabolism of many organophosphorous insecticides produces metabolites more toxic than the initial (or parent) compounds (eg, parathion to paroxan).

There are two phases of metabolism. Phase I includes oxidation, reduction, and hydrolysis mechanisms. These reactions, catalyzed by hepatic enzymes, generally convert foreign compounds to derivatives for Phase II reactions. Products of Phase I, however, may be excreted as such, if polar solubility permits translocation. Phase II principally involves conjugation or synthesis reactions. Common conjugates include glucuronides, acetylation products, and combinations with glycine. Metabolism of xenobiotic agents seldom follows a single pathway. Usually, a fraction is excreted unchanged, and the rest is excreted or stored as metabolites. Significant differences in metabolic mechanisms exist between species. For example, because cats lack forms of glucuronyl transferase, their ability to conjugate compounds such as morphine and phenols is compromised. Increased tolerance to subsequent exposures of a toxicant, in some instances, is due to enzyme induction initiated by the previous exposure.

Excretion: Excretion of most toxicants and their metabolites is by way of the kidneys. Some excretion occurs in the digestive tract and some via milk. Many polar and high-molecular-weight compounds are excreted into the bile. An enterohepatic cycle occurs when these compounds are excreted from the liver via bile, reabsorbed from the intestine, and returned to the liver. Milk is also an excretion pathway for some toxicants. The excretion rate may be of primary concern, because some toxicants can cause violative residues in food-producing animals. The route of administration, dose, and condition of the animal—to name a few factors—can have a profound effect on excretion rates. Toxicants are removed in the kidney by glomerular filtration, tubular excretion by passive diffusion, and active tubular secretion. The damage to the kidney from the excretion of xenobiotics is specific to the anatomic location where the excretion occurs. Excretion sites are proximal tubules, glomeruli, medulla, papilla, and loop of Henle. The proximal convoluted tubule is the most common site of toxicant-induced injury.

The important Phase I enzymes present in the kidney are cytochrome P450, prostaglandin synthase, and prostaglandin reductase. The Phase I enzyme cytochrome P450 is

present in the kidney at 10% of the level of the liver. Important Phase II enzymes present in the kidneys are UDP-glucuronosyltransferases (UGT), sulfotransferases, and glutathione-S-transferase.

The medulla and papilla are the target sites for phenylbutazone, the tubules are targets for many plant toxins, the loop of Henle is the target site for fluoride, and the glomeruli for immune complexes.

The elimination or disappearance (by metabolic change) of a chemical from an organ or the body is expressed in terms of **half-life** ($t_{1/2}$), defined as the amount of time required for the disappearance of half of the compound. The rate of elimination usually depends on the concentration of the compound. A constant fraction (eg, $1/2$) eliminated per unit of time is referred to as first-order kinetics. A metabolic reaction may dictate the rate of elimination. A constant amount eliminated per unit of time is referred to as zero-order kinetics. Different body compartments will likely have different elimination rates. A two-compartment system describes elimination that is initially rapid (eg, from the central or plasma component) and subsequently slower from the peripheral component (eg, liver, kidney, or fat).

FACTORS AFFECTING THE ACTIVITY OF TOXICANTS

Toxicosis potential is usually determined more by the multitude of related factors than by actual toxicity of the toxicant. Exposure-related, biologic, or chemical factors regulate absorption, metabolism, and elimination, and thus, influence observed clinical consequences.

Factors Related to Exposure: Dose is the primary concern; however, the exact intake of a toxicant is seldom known. Duration and frequency of exposure are important. The route of exposure affects absorption, translocation, and perhaps metabolic pathways. Exposure of a toxicant relative to periods of stress or food intake may also be a factor. After ingestion of some toxicants, emesis may occur if the stomach is empty, but if partly filled, the toxicant is retained and toxicosis can occur. Environmental factors, such as temperature, humidity, and barometric pressure, affect rates of consumption and even the occurrence of some toxic agents. Many mycotoxins and poisonous plants are correlated with seasonal or climatic changes. For example, the ischemic effects of ergot toxicosis are more often seen

during the winter cold, and plant nitrate levels are affected by rainfall amounts.

Biologic Factors: Various species and strains within species react differently to a particular toxicant because of variations in absorption, metabolism, or elimination. Functional differences in species may also affect the likelihood of toxicosis, eg, species unable to vomit can be intoxicated with a lower dose of some agents.

Age and size of the animal are primary factors in toxicosis. Metabolism and translocation of xenobiotic agents are compromised by the underdeveloped microsomal enzyme system in young animals. Membrane permeability and hepatic and renal clearance capabilities vary with age, species, and health. The amount of toxicant required to cause pathology is generally correlated to body weight, but with greater body weight, a disproportionate increase in toxicity (per unit body weight) of a compound often occurs. Body surface area may correlate more closely with the toxic dose. No measurement parameter is consistent for every situation.

Nutritional and dietary factors, hormonal and health status, organ pathology, stress, and sex all affect toxicosis. Nutritional factors may directly affect the toxicant (ie, by altering absorption) or indirectly affect the metabolic processes or availability of receptor sites. The copper-molybdenum-sulfate interaction is an example of both.

Chemical Factors: The chemical nature of a toxicant determines solubility, which in turn influences absorption. Nonpolar or lipid-soluble substances tend to be more readily absorbed than polar or ionized substances. The vehicle or carrier of the toxic compound also affects its availability for absorption. Isomers, including optical isomers, vary in toxicity. For example, the γ isomer of hexachlorocyclohexane (lindane) is more toxic than other isomers.

Adjuvants are formulation factors used to alter the toxicologic effect of the active ingredient (eg, piperonyl butoxide enhances the insecticidal activity of pyrethrins). Binding agents, enteric coating, and sustained-release preparations influence absorption of the active ingredient. As absorption is delayed, toxicity decreases. Flavoring agents affect palatability and thus the amount ingested.

DIAGNOSIS

Diagnosis of a toxicosis, as with any disease, is based on history, clinical signs,

lesions, laboratory examinations, and in some cases, analytical procedures. Circumstantial evidence is valuable and should be noted but does not replace a thorough clinical and postmortem examination. Histories from animal owners may stress obvious factors and omit subtle, important details. "Sudden death" is often actually "tardy observation," or sometimes the animal is simply found dead.

Pertinent data and samples should be submitted to the diagnostic laboratory. A complete history is necessary to develop the scheme of laboratory investigation and may be valuable in case of litigation. Information should be detailed. For example, a notation of CNS signs is insufficient; most animals exhibit some type of CNS signs before death. Exact actions and signs should be described. Examples of pertinent information include the following: 1) number of animals exposed/sick/dead, age, weight, and a chronology of morbidity and mortality; 2) clinical signs and course of the disease; 3) any prior disease conditions; 4) lesions seen at necropsy, with careful examination of ingesta; 5) response to treatment (medication should be listed to avoid analytic confusion); 6) related events, eg, feed change, water source, other medications, feed additives, pesticide applications; 7) description of facilities (a drawing or digital photograph may be helpful), access to refuse, machinery, etc; and 8) recent past locations and when moved. The diagnostic laboratory should be contacted if there are questions regarding the appropriate sample, amount, or container. (See also COLLECTION AND SUBMISSION OF LABORATORY SAMPLES, p 1584, and TABLE 1, GUIDELINES FOR SUBMITTING SAMPLES FOR TOXICOLOGIC EXAMINATION, p 1586.)

PRINCIPLES OF THERAPY

At initial examination, certain immediate, life-saving measures may be needed. Beyond this, treatment for toxicosis includes three basic principles: 1) prevention of further absorption, 2) supportive/symptomatic treatment, and 3) specific antidotes.

Prevention of Further Absorption:

Typically applied toxicants usually can be removed by thorough washing with soap and water; clipping of the hair or wool may be necessary. Emesis is of value in dogs, cats, and pigs if done within a few hours of ingestion. Emesis is contraindicated when the swallowing reflex is absent; the animal is convulsing; corrosive agents, volatile hydrocarbons, or petroleum distillates are involved; or risk of aspiration pneumonia is imminent.

Oral emetics include syrup of ipecac (10–20 mL, PO in dogs) and hydrogen peroxide (2 mL/kg, PO). Apomorphine can be used in dogs parenterally at a dosage of 0.05–0.1 mg/kg.

Gastric lavage, using an endotracheal tube and the largest bore stomach tube possible, is done on the unconscious or anesthetized animal. The head is lowered to a 30° angle, and 10 mL of lavage fluid (water or saline) per kg of body weight is gently flushed into the stomach and then removed. This process is repeated until returned fluid is clear. Cathartics and laxatives may be indicated in some instances for more rapid elimination of the toxicant from the GI tract. A gastrotomy or rumenotomy may be necessary when lavage techniques are insufficient (or too slow in ruminants).

When the toxicant cannot be physically removed, certain agents administered orally can adsorb it and prevent its absorption from the alimentary tract. Activated charcoal (1–2 g/kg) effectively adsorbs a wide variety of compounds and usually is the adsorbent and detoxicant of choice when toxicosis is suspected. The maximum amount of a drug adsorbed by activated charcoal is ~100–1,000 mg/g of charcoal. Sorbitol is sometimes added to activated charcoal to increase its palatability (in people) and to increase the GI transit time and flush out charcoal-bound toxins more rapidly. Activated charcoal should not be used in animals with known hypersensitivity or allergy to the drug. With administration of high doses, vomiting, constipation, or diarrhea may occur, and feces will appear black.

Supportive Therapy: Supportive therapy is often necessary until the toxicant can be metabolized and eliminated. The type of support required depends on the animal's clinical condition. Supportive efforts may include control of convulsive seizures, maintenance of respiration, treatment for shock, correction of electrolyte imbalance and fluid loss, and control of cardiac dysfunction, as well as alleviation of pain.

Specific Antidotes: Specific antidotes for various toxicants work by various mechanisms. Some complex with the toxicant (eg, the oximes bind with organophosphorous insecticides, and EDTA chelates lead). Others block or compete for receptor sites (eg, vitamin K competes with the receptor for coumarin anticoagulants). A few affect metabolism of the toxicant (eg, nitrite and thiosulfate ions release and bind cyanide).

TOXICOLOGIC HAZARDS IN THE WORKPLACE

Veterinarians are potentially exposed to myriad potent pharmaceuticals and other hazardous materials as part of their work environment, and particularly during patient decontamination procedures (most notably dermal decontamination). Therefore, knowledge of important toxicologic workplace hazards and basic personal protective equipment (PPE) is important. It is critical to recognize that PPE is the "last line of defense" and not a panacea for toxicologic hazards. The overarching principle is to avoid exposure if at all possible. Over-reliance on inadequately fitted or inappropriate types of PPE continues to be a substantial cause of human casualties because of the feeling of overconfidence these devices can provide. In particular, respirators should be selected, fitted, and tested by persons qualified to do this.

The following general PPE principles apply: The general minimum assumed PPE is long pants, a long-sleeved shirt, socks, closed footwear, and eye protection. Gloves with appropriate chemical resistance characteristics for a given situation should be used; gloves should be changed regularly, and double gloving done if necessary. If there is any risk of significant inhalation and eye exposure, a properly fitted full-face respirator and appropriate filters/cartridges should be used. If there is any doubt regarding air quality, it should be tested before entry into a potentially contaminated space (particularly if it is a potentially contaminated closed space). Anyone entering into a confined space should be able to be extracted/rescued without others needing to enter the space. If there is any question regarding the safety of the work environment, one should not work alone. Appropriate antidote kits (eg, cyanide antidote kit) should be readily available if relevant to the situation. Relevant human exposure guidelines and limits are set by local regulatory agencies.

Although this chapter is not meant to be a comprehensive discussion of every possible toxicologic workplace hazard faced by veterinarians, some common, important, and potentially lethal agents known to have caused injuries and fatalities to veterinarians are briefly discussed.

CARBON MONOXIDE

Carbon monoxide (CO) will most commonly be encountered by veterinarians working in enclosed spaces (eg, intensive animal production facilities) being heated by combustion sources (eg, gas space heating). Accordingly, this exposure most commonly occurs during cold weather and winter. Indeed, epidemics of fatal CO poisoning notoriously occur during extreme winter weather conditions, especially in conjunction with electrical power failures (ie, use of combustion heaters, electrical generators, combustion engines, combustion power tools, wood heaters, etc, in enclosed spaces without adequate ventilation). Like cyanide, CO is also a component of smoke inhalation poisoning. Inhalation is the main route of exposure to CO. CO poisoning is the most common form of fatal air poisoning in many countries.

CO is colorless and tasteless and has no odor, making it especially hazardous in occupational settings, particularly in enclosed spaces with inadequate ventilation. The use of CO monitors and/or testing of breathing air with a Dräger tube apparatus or similar test method are strongly recommended before entry into any environment where CO might be present. The use of CO monitors in animal production facilities being heated by combustion sources is strongly recommended.

CO binds to hemoglobin, forming carboxyhemoglobin and disrupting blood oxygen transport. The development of impaired hemoglobin oxygen transport can cumulatively progress over time because of the relatively slow reversal of carboxyhemoglobin to normal hemoglobin. Thus, CO poisoning can "creep up unexpectedly and without being noticed" over time. The signs and symptoms of CO poisoning in people are relatively nonspecific. One of the early and important indicators of exposure to excessive amounts of CO is development of a severe and persistent headache. Other common early clinical signs include dizziness, weakness, nausea, vomiting, chest pain, shortness of breath, irritability, and altered mental status. Loss of consciousness, coma, and death can occur. Other signs and symptoms include

tachycardia, tachypnea, hypotension, various neurologic findings (including impaired memory and cognitive and sensory disturbances), metabolic acidosis, arrhythmias, myocardial ischemia or infarction, and noncardiogenic pulmonary edema; any organ system can be involved. Many survivors of severe CO poisoning have hypoxic brain injuries, which can be associated with personality changes, memory deficits, disturbances in voluntary muscle movements, and the appearance of involuntary movements (extrapyramidal syndromes).

Persons with significant CO poisoning have been described as having a "healthy" red complexion and mucous membranes because of the presence of high levels of carboxyhemoglobin. Normal pulse oximeters will not detect the presence of carboxyhemoglobin; pulse co-oximetry is required. Additionally, blood carboxyhemoglobin levels correlate poorly with the clinical severity of the poisoning.

There is no specific antidote for CO poisoning. Resuscitation combined with oxygen is the only known effective approach to treatment. Rescue and treatment of individuals with CO poisoning is a matter for properly equipped and trained professionals.

CYANIDE

Important sources of exposure in veterinary medicine include rumen contents of grazing animals that have consumed or been poisoned with plant cyanogenic glycosides (eg, during necropsy/sample collection procedures), handling or exposure to cyanide vertebrate pesticide agents (or animals poisoned by them), and combustion sources (particularly of nitrogen-containing materials such as plastics, wool, silk). Aqueous solutions of cyanide are commonly referred to as prussic acid, and hydrocyanic acid and formonitrile are commonly used synonyms. (See *also* CYANIDE POISONING, p 2959.)

Solutions of hydrogen cyanide are colorless or pale-blue liquid at room temperature. Cyanide is very volatile and highly toxic, and flammable/explosive concentrations can rapidly develop at normal temperatures and pressures, especially in enclosed spaces.

Hydrogen cyanide gas has a distinctive, bitter almond smell; however, the ability of people to detect the odor is genetically determined. Anosmic individuals (20%–40% of the human population) are not able to detect it. Accordingly, odor detection cannot be relied on in terms of detection

and warning in relation to exposure. The wearing of cyanide detection devices and/or testing of breathing air with a Dräger tube apparatus or similar test method is strongly recommended before entry into any environment where cyanide might be present.

The major potential route of workplace exposure in veterinary medicine is by inhalation. Substantial skin absorption can occur if the atmospheric concentration is high or if the skin comes into contact with cyanide solutions. High ambient temperatures and high humidity appear to increase skin absorption. Skin or clothing contamination with cyanide-containing materials can result in off-gassing of cyanide vapor and inhalation. Exposure by any route can cause systemic toxicity. Cyanide is also a skin and eye irritant. Children are more susceptible to poisoning because of their higher minute ventilation per kg body wt.

Significant cyanide exposures result in death within a few minutes because of the arrest of mitochondrial oxidative phosphorylation, histotoxic hypoxia, and severe metabolic acidosis, which results in rapid onset CNS, cardiovascular, and respiratory effects. CNS signs and symptoms in people develop very quickly and are nonspecific: excitement, dizziness, nausea, vomiting, headache, and weakness, which progresses to drowsiness, tetanic spasm, lockjaw, convulsions, hallucinations, loss of consciousness, and terminal coma. Cardiovascular signs include arrhythmias and intractable hypotension. Respiratory signs typically include shortness of breath and chest tightness, rapid breathing, and increased depth of respirations progressing to agonal respiration. Pulmonary edema and cyanosis of the skin may or may not be present. Severe, intractable anion-gap metabolic acidosis due to lactic acidosis typically develops rapidly. Cyanide poisoning survivors usually develop some form of hypoxic brain damage, and this can be associated with personality changes, memory deficits, disturbances in voluntary muscle movements, and appearance of involuntary movements (extrapyramidal syndromes).

Victims exposed only to hydrogen cyanide gas do not pose secondary contamination risks to rescuers, but resuscitation without a barrier should not be attempted. Victims whose clothing or skin is contaminated with hydrogen cyanide liquid or solution can secondarily contaminate response personnel by direct contact or through off-gassing vapor. Dermal contact with cyanide-contaminated victims

or with gastric contents of victims who may have ingested cyanide-containing materials should be avoided.

Veterinarians poisoned by cyanide require speedy treatment, rapid administration of antidotes, and specialist care. Great care should be taken by rescuers who plan to enter a contamination "hot zone." Many human casualties have occurred because of well-intentioned but misguided attempts at rescue from hydrogen cyanide-contaminated hot zones. Rescue and emergency treatment is best left to those with specialized training in these areas.

HYDROGEN SULFIDE

Veterinarians are most likely to encounter hydrogen sulfide emanating from concentrated decaying organic matter (eg, septic/sewage ponds/manure handling facilities in intensive animal production facilities, rotting feed stores, carcass pits, etc).

When near sewage ponds, it is particularly important not to disturb the surface of the pond or to cause mixing of the contents, because this will trigger degassing of dissolved hydrogen sulfide.

Hydrogen sulfide is a colorless, flammable, and very rapidly toxic gas. Hydrogen sulfide is slightly heavier than air, tends to accumulate in low-lying, poorly ventilated spaces, and is highly flammable and explosive. It has a characteristic rotten-egg odor that can be sensed at concentrations as low as 0.5 ppb. However, the sensitivity to hydrogen sulfide odor is genetically determined, and a significant proportion of the human population has poor odor detection ability to this gas; additionally, extended exposure (2–15 min at 100 ppm) to hydrogen sulfide results in paralysis of the olfactory nerve, resulting in a loss of ability to detect the gas. Therefore, odor is not a reliable indicator of the presence of hydrogen sulfide and cannot be relied on to provide a warning of hazardous concentrations. The use of hydrogen sulfide monitors and/or testing of breathing air with a Dräger tube apparatus or similar test method are strongly recommended before entry into any environment where hydrogen sulfide might be present.

Veterinarians are typically exposed to hydrogen sulfide via inhalation. Children are more susceptible because of their high minute volume to weight ratio and higher lung surface area to body weight ratio. Prolonged exposure to hydrogen sulfide is notably irritating to the skin and eyes.

Hydrogen sulfide is also a notable mucous membrane and respiratory tract irritant, and the acute and/or delayed (up to 72 hr after exposure) respiratory distress syndromes are common sequela of prolonged inhalation exposure to nonacutely fatal levels of hydrogen sulfide.

Hydrogen sulfide acts by inactivating mitochondrial cytochrome oxidase, resulting in the failure of oxidative metabolism, histotoxic hypoxia, and acute anion-gap metabolic acidosis. Its mode of action resembles that of cyanide. Acute exposure to high concentrations of hydrogen sulfide will result in sudden collapse and death due to central respiratory failure (hydrogen sulfide knock-down effect) caused by its peracute effects on the brain. Signs and symptoms of acute exposure include initial CNS stimulation, nausea, headaches, impaired gait, dizziness, disturbed equilibrium, tremors, convulsions, skin and eye irritation, coma, respiratory paralysis, and death. Many survivors of acute hydrogen sulfide poisoning have hypoxic brain and cardiac injuries. Hypoxic brain damage can be associated with personality changes, memory deficits, disturbances in voluntary muscle movements, and appearance of involuntary movements (extrapyramidal syndromes).

Low concentrations of hydrogen sulfide (~50 ppm) rapidly produce upper respiratory tract irritation, and prolonged exposure can result in pulmonary irritation (cough, shortness of breath, and bronchial or lung hemorrhage, bronchitis, and immediate or delayed pulmonary edema). Cyanosis may be present. Hydrogen sulfide inhalation is associated with cardiac arrhythmias. Nausea and vomiting are also common.

Chronic, repeated, lower-level hydrogen sulfide exposure is associated with hypotension, headache, nausea, loss of appetite, weight loss, ataxia, conjunctivitis, chronic cough, and neuropsychological disorders.

Ill-advised and poorly equipped attempts at rescuing victims from hydrogen sulfide-contaminated hot zones have resulted in large numbers of hydrogen sulfide-associated human casualties. There is currently no effective antidote for hydrogen sulfide poisoning. Resuscitation combined with oxygen is the only known effective approach to treatment. Rescue and treatment of individuals with hydrogen sulfide poisoning is a matter for properly equipped and trained professionals.

NITROGEN DIOXIDE

(Silo filler's disease)

Veterinarians are most likely to encounter nitrogen dioxide in association with grain silos, grain silo chutes in intensive animal production facilities, silage, silage bags, and silage pit vents. When a silo or pit is filled with fresh organic material (grain, grass etc), nitrogen dioxide is formed by anaerobic fermentation. High levels can develop at the top of grain in silos or at the top of silage pits within hours of their filling. Veterinarians working in or around silo chutes and hatches or silage pits or silage bags during the first 10 days or so after fill will be exposed to nitrogen dioxide. Silo chutes and other nearby structures exposed to significant levels of nitrogen dioxide are often stained yellow to red by the gas.

Nitrogen dioxide is a reddish, water-insoluble, reactive gas with a characteristic pungent odor. Because of its low water solubility, it is not scrubbed by the upper respiratory tract. It penetrates deeply into the lung, where it is reactive with lung surface fluids and acts as a pulmonary irritant. When nitrogen dioxide contacts the lung surface fluids, it slowly hydrolyzes to nitrous and nitric acid, producing chemical pneumonitis and pulmonary edema.

Acute, high-level exposures to nitrogen dioxide result in acute respiratory distress syndrome in people, which is characterized by rapid or delayed onset (up to 72 hr after exposure) progressive pulmonary edema and respiratory failure. Nitrogen dioxide acute respiratory distress syndrome is less common than other toxic injuries, because the pungent odor and other effects of nitrogen dioxide usually trigger an escape from the source of exposure. This type of severe effect is more likely if the affected person cannot escape.

More common acute signs and symptoms include cough, light-headedness, dyspnea, chest tightness, choking, sweating, chest pain, and wheezing. Because of nitrogen dioxide's low water solubility, mucous membrane and eye irritation are relatively uncommon signs.

Usually of greater concern is the capacity of nitrogen dioxide inhalation to induce sometimes severe delayed effects, including bronchiolitis obliterans (fever, cough, and dyspnea), respiratory insufficiency new-onset asthma, COPD, and hypoxia/cyanosis.

There is no specific antidote for nitrogen dioxide poisoning. Treatment requires specialist medical care.

PHOSPHINE GAS SOURCES

Phosphide salts (commonly zinc and aluminum) release phosphine gas in the presence of acids and have been extensively used as vertebrate pesticides. Veterinarians are most commonly exposed to phosphine via inhalation when attempting to decontaminate and treat animals that have been poisoned with zinc or aluminum phosphide rodenticides or during necropsy/sample collection procedures on animals that died from these poisonings. Phosphine gas is also used as a fumigant for grain and other agricultural products.

Phosphine is a colorless, flammable, and explosive gas. Technical grade phosphine (the type most commonly encountered by veterinarians) has an unpleasant, garlic-like, rotting fish-like smell, due to the presence of substituted phosphine and diphosphane. The human odor threshold for phosphine is below relevant exposure limits; the implication is that persons who can smell phosphine are being exposed to a hazardous level.

Phosphine is described as a "general protoplasmic poison," and it is extremely and acutely toxic after inhalation. Acute inhalation exposure to phosphine can result in respiratory, neurologic, and GI effects. Signs and symptoms may include headaches, dizziness, fatigue, drowsiness, burning substernal pain, nausea, vomiting, GI distress, cough with fluorescent green sputum, labored breathing, chest tightness, pulmonary irritation, pulmonary edema, tremors, and convulsions (may occur after apparent recovery). Skin contact with phosphides may result in numbness and paresthesia. Chronic occupational exposure effects include upper respiratory tract inflammation, weakness, dizziness, nausea, jaundice, liver effects, increased bone density, and symptoms referable to the GI, cardiorespiratory, and central nervous systems.

Veterinarians are very strongly encouraged to use respiratory and eye protection when dealing with patients poisoned by zinc or aluminum phosphide; emergency room staff casualties have occurred during treatment of human patients poisoned with these agents.

There is no antidote for phosphine poisoning, and emergency treatment requires specialist care.

LACK OF OXYGEN

Veterinarians commonly encounter low-oxygen environments in enclosed spaces that contain biologically respiring

materials. Freshly cut plant material will continue to be metabolically active, and thus potentially consume oxygen from the air, for surprisingly long periods of time. If such materials (eg, grains, hays, freshly cut timber, etc) are stored in sealed confined spaces (eg, silos, ship holds, etc) with little ventilation, a low-oxygen atmosphere will develop. Such circumstances have resulted in significant human casualties and deaths. Such environments should always be treated with suspicion, and their atmosphere tested for the presence of breathable air; testing with a flame is not an adequate method. It is strongly recommended that individuals do not work alone in such environments and that a method of safe extraction of a person entering into such environments is immediately available.

Entry into low-oxygen environments can result in rapid loss of consciousness and death. Typical signs and symptoms of hypoxia include lightheadedness, fatigue, numbness, tingling of extremities, nausea, ataxia, confusion, disorientation, hallucinations, behavioral change, severe headaches, reduced consciousness, papilledema, breathlessness, pallor, tachycardia, and tachypnea, with eventual progression to cyanosis, slow heart rate/cor pulmonale and low blood pressure, and death.

Ill-considered and poorly equipped rescue attempts from low-oxygen environments have resulted in many human casualties. Rescue operations under such circumstances are best performed by properly equipped and trained professionals.

ALGAL POISONING

Algal poisoning is an acute, often fatal condition caused by high concentrations of toxic blue-green algae (more commonly known as cyanobacteria—literally blue-green bacteria) in drinking water as well as in water used for agriculture, recreation, and aquaculture. Fatalities and severe illness of livestock, pets, wildlife, birds, and fish from heavy growths of cyanobacteria waterblooms occur in almost all countries of the world. Acute lethal poisonings have also been documented in people. Poisoning usually occurs during warm seasons when the waterblooms are more intense and of longer duration. Most poisonings occur among animals drinking cyanobacteria-infested freshwater, but aquatic animals, especially maricultured fish and shrimp, are also affected. The toxins of cyanobacteria comprise six distinct chemical classes collectively called cyanotoxins.

Etiology, Epidemiology, and Pathogenesis:

Although toxic strains within species of *Anabaena*, *Aphanizomenon*, *Cylindrospermopsis*, *Microcystis*, *Nodularia*, *Nostoc*, *Oscillatoria*, and *Planktothrix* are responsible for most cases of toxicity, there are >30 species of cyanobacteria that can be associated with toxic waterblooms. Neurotoxic alkaloids (called anatoxins) can be produced by

Anabaena, *Aphanizomenon*, and *Planktothrix*, while saxitoxins (also called paralytic shellfish toxins) can be produced by *Anabaena*, *Aphanizomenon*, and *Lyngbya*. Hepatotoxic heptapeptides called microcystins can be produced by *Anabaena*, *Microcystis*, *Nostoc*, and *Planktothrix*. The brackish water genus *Nodularia* produces a hepatotoxic pentapeptide related, in both structure and function, to microcystins. *Cylindrospermopsis*, *Anabaena*, *Aphanizomenon*, *Raphidiopsis*, and *Umezakia* can produce a potent hepatotoxic alkaloid called cylindrospermopsin. Some genera, especially *Anabaena*, can produce both neuro- and hepatotoxins. If a toxic waterbloom contains both types of toxins, the neurotoxin signs are seen first, because their effects occur much sooner (minutes) than those of the hepatotoxins (1 to a few hours). Other noncyclic peptides and amino acids produced by cyanobacteria can also have biological activity. One recent amino acid with neurologic degenerative activity is BMAA (β-methylamino alanine). BMAA has been implicated as the causative agent of amyotrophic lateral sclerosis or parkinsonism dementia.

Poisoning usually does not occur unless there is a heavy waterbloom that forms a dense surface scum. Factors that contribute to heavy waterblooms are nutrient-rich

eutrophic to hypereutrophic water and warm, sunny weather. Evidence supports the observation that global climate change causes earlier, more intense, and longer-lasting warm weather that leads to more extensive waterblooms of cyanobacteria. Agriculture practices (eg, runoff of fertilizers and animal wastes) that promote nutrient enrichment also contribute to and intensify waterbloom formation. The problem is augmented by light winds or wind conditions that lead to areas of very high (scum) concentrations of cyanobacteria, especially leeward shoreline locations where livestock drink. Experiments with both toxin groups have revealed a steep dose-response curve, with as much as 90% of the lethal dose being ingested without measurable effect. Animal size and species sensitivity influence the degree of intoxication. Monogastric animals are less sensitive than ruminants and birds. Depending on waterbloom densities and toxin content, animals may need to ingest only a few ounces to be affected. However, if the waterbloom is less dense or cyanotoxin content is low, as much as several gallons may be needed to cause acute or lethal toxicity. Among domestic animals, dogs are most susceptible to a toxic waterbloom. This is due to their preference for swimming and drinking in dense waterblooms and a greater species sensitivity to the cyanotoxins, especially the neurotoxins.

Although the species sensitivity and signs of poisoning can vary depending on the type of exposure, the gross and histopathologic lesions are quite similar among species poisoned by the hepatotoxic peptides and neurotoxic alkaloids. Death from hepatotoxicosis induced by cyclic peptides is generally accepted as being the result of intrahepatic hemorrhage and hypovolemic shock. This conclusion is based on large increases in liver weight as well as in hepatic hemoglobin and iron content that account for blood loss sufficient to induce irreversible shock. In animals that live more than a few hours, hyperkalemia or hypoglycemia, or both, may lead to death from liver failure within a few days to a few weeks.

Neurotoxicosis, with death occurring in minutes to a few hours from respiratory arrest, may result from ingestion of the cyanobacteria that produce neurotoxic alkaloids. Species and strains of *Anabaena*, *Aphanizomenon*, *Oscillatoria*, and *Planktothrix* can produce a potent, postsynaptic cholinergic (nicotinic) agonist called anatoxin-a that causes a depolarizing neuromuscular blockade. Strains of *Anabaena* can produce an irreversible

organophosphate anticholinesterase called anatoxin-a(s). *Anabaena*, *Aphanizomenon*, *Cylindrospermopsis*, and *Lyngbya* can produce the potent, presynaptic sodium channel blockers called saxitoxins.

Clinical Findings and Lesions: One of the earliest effects (15–30 min) of microcystin poisoning is increased serum concentrations of bile acids, alkaline phosphatase, γ -glutamyltransferase, and AST. The WBC count and clotting times increase. Death may occur within a few hours (usually within 4–24 hr), up to a few days. Death may be preceded by coma, muscle tremors, paddling, and dyspnea. Watery or bloody diarrhea may also be seen. Gross lesions include hepatomegaly due mostly to intrahepatic hemorrhage. Intact clumps of greenish cyanobacteria can be found in the stomach and GI tract, and there is a greenish stain on the mouth, nose, legs, and feet. Hepatic necrosis begins centrilobularly and proceeds to the periportal regions. Hepatocytes are disassociated and rounded. After death, debris from disassociated hepatocytes can be found in the pulmonary vessels and kidneys. Clinical signs of neurotoxicosis progress from muscle fasciculations to decreased movement, abdominal breathing, cyanosis, convulsions, and death. Signs in birds are similar but include opisthotonos. In smaller animals, death is often preceded by leaping movements. Cattle and horses that survive acute poisoning may have signs of photosensitization in areas exposed to light (nose, ears, and back), followed by hair loss and sloughing of the skin.

Diagnosis: Diagnosis is based primarily on history (recent contact with cyanobacteria waterbloom), signs of poisoning, and necropsy findings. Samples of the waterbloom should be taken as soon as possible for microscopic examination to confirm the presence of the toxigenic cyanobacteria and for cyanotoxin analysis. Although there are nontoxic and toxic strains of all the known toxic species, it is not possible to identify a toxic strain by visual examination. Cyanobacteria are detected by light microscopy, identified using morphologic characteristics, and counted per standard volume of water. Standard protocols to sample and monitor cyanobacteria as well as practical keys for the identification of toxic species are available.

Some laboratories can analyze for the cyanotoxins either by chemical or biologic assay. Animal bioassays (mouse tests) have traditionally been used to detect the

presence of the entire range of cyanotoxins based on survival times and signs of poisoning. These tests provide a definitive indication of toxicity, although they cannot be used for precise quantification of compounds in water or to determine compliance with standards for environmental levels. A number of analytic techniques are available to determine microcystins in water. These techniques must provide for quantitative comparison to the guideline or regulatory value in terms of toxicity equivalents. The method most suitable in this regard is high-performance liquid chromatography (HPLC) or HPLC coupled with mass spectrometry. These methods still involve estimation of the concentration and therefore provide only an estimate of toxicity. This is largely due to the limited availability of certified reference standards for the cyanotoxins. Commercial reference materials, purified from laboratory cultures or waterbloom material, for some microcystins, nodularin, cylindrospermopsin, and saxitoxins are available. A synthetic reference material for anatoxin-a is also available. No known commercial reference material is available for anatoxin-a(s). Newer methods of immunoassay, for quantification purposes, are also available. These include commercial ELISA kits in both laboratory and field formats for microcystins/nodularin, cylindrospermopsin, and saxitoxins. Also available is a receptor-binding assay colorimetric plate kit for anatoxin-a.

Treatment: After removal from the contaminated water supply, affected animals should be placed in a protected area out of direct sunlight. Ample quantities of water and good quality feed should be made available. Because the toxins have a steep dose-response curve, surviving animals have a good chance for recovery. Although therapies for cyanobacterial poisonings have not been investigated in detail, activated charcoal slurry is likely to be of benefit. In laboratory studies, an ion-exchange resin such as cholestyramine has proved useful to absorb the toxins from the GI tract, and certain bile acid transport blockers such as cyclosporin A, rifampin, and silymarin injected before dosing of microcystin have effectively prevented hepatotoxicity. No therapeutic antagonist has been found effective against anatoxin-a, cylindrospermopsin, or the saxitoxins, but atropine and activated charcoal reduce the muscarinic effects of the anticholinesterase anatoxin-a(s).

Prevention: Removal of animals from the affected water supply is essential. If no

other water supply is available, animals should be allowed to drink only from shore areas kept free (by prevailing winds) of dense surface scums of cyanobacteria. Some efforts have been made to erect surface barriers (logs or floating plastic booms) to keep shore areas free of surface scum, but these are not very successful. Cyanobacteria can be controlled by adding copper sulfate (CuSO_4) or other copper-based algicidal treatments to the water. The usual treatment for CuSO_4 is 0.2–0.4 ppm, equivalent to 0.65–1.3 oz/10,000 gal. of water or 1.4–2.8 lb/acre-foot of water. Livestock (especially sheep) should not be watered for at least 5 days after the last visible evidence of the cyanobacteria waterbloom. CuSO_4 is best used to prevent waterbloom formation, and care should be taken to avoid water that has dead cyanobacteria cells, either from treatment with algicide or natural aging of the bloom, because most toxin is released in the water only after breakdown of the intact cyanobacteria cells. A chemical control method receiving attention are compounds to bind and remove phosphorus from eutrophic waters. This has the potential to minimize one of the more important nutrients responsible for cyanobacteria waterblooms. Common phosphorus treatments include lime, aluminum sulfate, ferric chloride, and some types of clay particles. These treatments also act as flocculating agents and form particulates with algae cells and other debris that settle out and remove the bloom from the water column. For example, when alum (potassium aluminum sulfate) is used in a water supply, a precipitate (floc) forms that carries algae cells, dirt, and bacteria to the bottom, but charged items such as phosphate and colloids are bound by the same precipitate through their charges. A newer, effective phosphorus-binding compound product available in the USA since 2010 uses a patented phosphorus-locking technology containing lanthanum (5%), a naturally occurring earth element, embedded inside a clay matrix (~95%).

Source water management techniques for control of cyanobacterial growth include flow maintenance in regulated rivers, water mixing techniques both to eliminate stratification and reduce nutrient release from sediments in reservoirs, and the use of algicides in dedicated water supply storages. Algicides disrupt cells and liberate intracellular toxins. Algicide use should be in accordance with local environment and chemical registration regulations. In situations where multiple offtakes are available, the selective withdrawal of water

from different depths can minimize the intake of high surface accumulations of cyanobacterial cells.

Water treatment techniques can be highly effective to remove both cyanobacterial cells and cyanotoxins (especially microcystins) with the appropriate technology. Most cyanotoxins remain intracellular, unless the cells are lysed or damaged from age or stress from water conditions or chemical treatment. The one exception is cylindrospermopsin, which is actively secreted from even healthy cells. This makes it possible to remove cells and cyanotoxins (especially microcystins) by coagulation and filtration in a conventional treatment plant. Treatment of water containing cyanobacterial cells with oxidants such as chlorine or

ozone, while killing cells, will result in the release of free cyanotoxin. Therefore, the practice of prechlorination or preozonation is not recommended without a subsequent step to remove dissolved cyanotoxins.

Microcystins are readily oxidized by a range of oxidants, including ozone and chlorine. Adequate contact time and pH control are needed to achieve optimal removal of these compounds, which is more difficult in the presence of whole cells. Microcystins, anatoxin-a, cylindrospermopsin, and some saxitoxins are also adsorbed from solution by both granular activated carbon and, less efficiently, by powdered activated carbon. The effectiveness of the process should be determined by monitoring cyanotoxin in the product water.

CYANIDE POISONING

In acute cyanide poisoning, cyanide ions (CN^-) bind to, and inhibit, the ferric (Fe^{3+}) heme moiety form of mitochondrial cytochrome c oxidase (synonyms: aa₃, complex IV, cytochrome A3, EC 1.9.3.1). This blocks the fourth step in the mitochondrial electron transport chain (reduction of O_2 to H_2O), resulting in the arrest of aerobic metabolism and death from histotoxic anoxia. Tissues that heavily depend on aerobic metabolism such as the heart and brain are particularly susceptible to these effects. Cyanide also binds to other heme-containing enzymes, such as members of the cytochrome p450 family, and to myoglobin. However, these tissue cyanide "sinks" do not provide sufficient protection from histotoxic anoxia. The acute lethal dosage of hydrogen cyanide (HCN) in most animal species is ~2 mg/kg. Plant materials containing ≥ 200 ppm of cyanogenic glycosides are dangerous.

There are at least two forms of chronic cyanide poisoning in domestic animals: 1) hypothyroidism due to disruption of iodide uptake by the follicular thyroid cell sodium-iodide symporter by thiocyanate, a metabolite in the detoxification of cyanide, and 2) chronic cyanide and plant cyanide metabolite (eg, various glutamyl β -cyanoalanines)–associated neuropathy toxidromes (eg, equine sorghum cystitis ataxia syndrome, cystitis ataxia syndromes in cattle, sheep, and goats).

Etiology: Various chemical forms of cyanides are found in plants, fumigants, soil sterilizers, fertilizers (eg, cyanamide), pesticides/rodenticides (eg, calcium cyanomide) and salts used in industrial processes, such as gold mining, metal cleaning and electroplating, photographic processes, and others. Hydrogen cyanide is also known as prussic acid, and cyanide salts liberate cyanide gas in the presence of acids (eg, in the stomach). Cyanide preparations are still used as vertebrate pest control agents for control of feral pigs, fox, Australian brush-tailed possums, and other pest or predator species in a number of countries. Cyanide salts are still used as killing agents in entomology and (illegally) as a method of fishing and/or collection of aquarium fish species (ie, cyanide fishing). Combustion of common polyacrylonitriles (plastics), wool, silk, keratin, polyurethane (insulation/upholstery), melamine resins (household goods), and synthetic rubber results in the release of cyanide gas. Car fires are notorious sources of cyanide exposure, and cyanide is also a notable component of internal combustion engine exhaust and tobacco smoke. Carbon monoxide poisoning with cyanide gas is thus an extremely common component of smoke inhalation toxidromes.

Toxicity can result from accidental, improper, or malicious use or exposure. However, in livestock species, the most

frequent cause of acute and chronic cyanide poisoning is ingestion of plants that either constitutively contain cyanogenic glycosides or are induced to produce cyanogenic glycosides and cyanolipids as a protective response to environmental conditions (plant cyanogenesis). Plant cyanogenesis is a common process and has been documented in >3,000 different plant species distributed over ~110 different families of ferns, gymnosperms, and angiosperms. Of these plants, ~300 species are potential causes of acute and chronic cyanogenic glycoside poisoning, and there are ~75 different cyanogenic glycosides (all of which are O- β -glycosidic derivatives of α -hydroxynitriles). Plant species of notable veterinary importance include *Sorghum* spp (Johnson grass, Sudan grass, and *S bicolor*, the common cereal grain crop referred to as "sorghum" or the synonyms durra, jowari, milo), *Acacia greggii* (guajillo), *Amelanchier alnifolia* (western service berry), *Linum* spp (linseeds and flaxes), *Sambucus nigra* (elderberry), *Suckleya suckleyana* (poison suckleya), *Triglochin maritima* and *T palustris* (marsh arrow grasses), *Mannihot esculentum* (cassava), all members of the *Prunus* genus until proved otherwise (apricot, peach, chokecherry, pincherry, wild black cherry, ornamental cherry, peaches, nectarines, apricots, almonds, bird cherries, black thorn, cherry laurels [commercial orchard species are often specifically bred for low cyanide content; however, ornamental members of this genus are often highly poisonous]), *Nandina domestica* (heavenly or sacred bamboo), *Phaseolus lunatus* (lima beans), members of the *Vicia* genus until proved otherwise (vetches; often, pasture species have been bred for low cyanogenesis), *Lotus* spp (bird's-foot trefoils; often, pasture species have been bred for low cyanogenesis), *Trifolium* sp (clovers; often, pasture species have been bred for low cyanide content), *Zea mays* (corn), *Eucalyptus* spp (gum trees), *Hydrangea* spp (hydrangeas), *Peridium aquilinum* (bracken fern), *Bahia oppositifolia* (bahia), and *Chaenomeles* spp (flowering quince) (See also SORGHUM POISONING, p 3155). A number of insect species are also able to synthesize hydrogen cyanide and/or sequester hydrogen cyanide that is derived from the cyanogenic glycosides of their plant hosts (notably the USA eastern tent caterpillar *Malacosoma americanum* that is associated with mare reproductive loss syndrome (see also MARE REPRODUCTIVE LOSS SYNDROME, p 1343); however, cyanide is not the cause of mare reproductive loss

syndrome. Invertebrates such as Burnet moths (*Zygaena* spp) that feed on bird's-foot trefoils), as well as certain centipede and millipedes, are potentially hazardous food sources for exotic pet species.

Plant cyanogenesis in response to environmental stressors is an important part of the etiology and risk of acute cyanogenic glycoside poisoning. Within plants, amino acids that are not used for protein synthesis can be metabolized to α -hydroxynitriles and then to cyanogenic glycosides. Plants are protected from the potential adverse effects of cyanogenic glycosides by two features: cyanogenic glycosides are largely found within cell vacuoles, and the presence of the detoxifying enzyme β -cyanoalanine synthase (which is responsible for production of some of the cyanide derivatives putatively involved in the chronic cyanide-associated neurologic toxidromes). Even so-called "acyanogenic" plants can become toxic under appropriate environmental circumstances. Environmental conditions that damage relevant plant species, reduce protein synthesis, enhance the conversion of nitrate to amino acids in the presence of reduced protein synthesis, and/or inhibit β -cyanoalanine synthase potentially increase the risk of cyanogenesis. Relevant environmental factors include crushing, wilting, freezing, high environmental temperatures, herbicide treatment, water stress, cool moist growing conditions, nitrate fertilization, high soil nitrogen:phosphorus ratios, soil phosphorus deficiency, low soil sulfur (decreases detoxification of cyanogenic glycosides to thiocyanates within plants), insect attack, and various plant diseases. Herbicide treatment of plants is important in that it may also increase plant palatability. Crushing and/or mastication of potentially cyanogenic plants is important in development of the acute toxidrome, because this releases cyanogenic glycosides from plant cell vacuoles and exposes them to catabolism by β -glucosidase and hydroxynitrile lyase present in the plant cell cytosol. Young, rapidly growing areas of plants and areas of regrowth after cutting often have high cyanogenic glycoside content. As a rough approximation, rapidly growing *Sorghum* spp are often hazardous until they reach ~60 cm in height; however, this is no guarantee of safety, and if there is any doubt regarding cyanogenic potential, samples of potential forage should be tested. Plant seeds and leaves typically have higher cyanogenic potential, while the fleshy parts of fruits generally have low levels. Drying often increases the cyanogenic potential of

plants, whereas ensiling may reduce cyanide content by ~50%.

β -glucosidase and hydroxynitrile lyase are also present in the rumen microflora, and a rumen pH of ~6.5–7 favors conversion of cyanogenic glycosides to cyanide. Ruminants on high-energy grain rations are somewhat less susceptible, because their lower rumen pH (~4–6) reduces the formation of cyanide. Consumption of water before grazing on cyanogenic pastures appears to increase the risk. Monogastric animals with low stomach pH are also somewhat less susceptible to cyanogenic glycoside poisoning. However, these factors do not guarantee immunity from poisoning.

Under conditions of low-level exposure, mammals detoxify ~80% of ingested cyanide to thiocyanate via mitochondrial rhodanese. Thiocyanate is then largely excreted in urine. Often, the rate of the rhodanese pathway is limited by the availability of thiosulfate; also notably, dogs have lower overall rhodanese activity than other species. Minor, but toxicologically important, pathways of detoxification in mammals include the combination of cyanide with hydroxycobalamin (vitamin B_{12a}) to yield cyanocobalamin (vitamin B₁₂), and the nonenzymatic combination of cyanide with cysteine to form β -thiocyanoalanine, which is converted to 2-iminothiazolidine-4-carboxylic acid and subsequently excreted. Small amounts of β -thiocyanoalanine are also excreted in saliva. Dietary levels of sulfur amino acids (L-cysteine and L-methionine) strongly influence the rate of detoxification of cyanide, and low dietary intakes are associated with higher blood cyanide levels, particularly under conditions of chronic, low level exposure. Dietary sulfur and sulfur amino acid intake are known to strongly affect the neurologic toxidromes associated with chronic cyanide/cyanogenic glycoside exposure in people.

Chronic low-level cyanide/cyanogenic glycoside exposure is associated with increased exposure to the cyanide metabolite thiocyanate. Under conditions of thiocyanate overload, thiocyanate acts as a competitive inhibitor of thyroid follicular cell iodine uptake by the sodium/iodide symporter. This results in reduced iodination of tyrosine, reduced T₃ synthesis, increased blood TSH, goiter, and hypothyroidism. Similar effects occur with some plant glucosinolates (goitrogenic glycosides). Selenium deficiency appears to enhance these effects.

Chronic, low-level cyanide/cyanogenic glycoside exposure (often in combination with low dietary sulfur and/or sulfur amino

acid intake) is associated with neuropathy syndromes in horses and ruminants. Sorghum cystitis ataxia syndrome of horses is associated with diffuse nerve fiber degeneration in the lateral and ventral funiculi of the spinal cord and brain stem. Similar syndromes have been described in ruminants. Comparisons between these syndromes as chronic cyanogenic glycoside-associated human myeloneuropathies such as Konzo and tropical ataxic neuropathy have been made; however, the precise toxins and modes of action are yet to be fully defined. All of these toxidromes appear to be related to a combination of chronic cyanide/cyanogenic glycoside exposure combined with low dietary sulfur and/or sulfur amino acid intake and possibly other nutritional deficiencies. Lathrogenic plant cyanide metabolites such as β -cyanoalanine have been implicated as causative or at least contributory agents.

Chronic, low-level cyanogenic glycoside exposure (notably from *Sorghum* spp) has been associated with musculoskeletal teratogenesis (ankyloses or arthrogryposes) and abortion.

Clinical Findings: *Acute cyanide poisoning:* Signs generally occur within 15–20 min to a few hours after animals consume toxic forage, and survival after onset of clinical signs is rarely >2 hr. Excitement can be displayed initially, accompanied by rapid respiration rate. Dyspnea follows shortly, with tachycardia. The classic “bitter almond” breath smell may be present; however, the ability to detect this smell is genetically determined in people, and anosmic people (a significant proportion of the population) cannot detect it. Salivation, excess lacrimation, and voiding of urine and feces may occur. Vomiting may occur, especially in pigs. Muscle fasciculation is common and progresses to generalized spasms and coma before death. Animals may stagger and struggle before collapse. In other cases, sudden unexpected death may ensue. Mucous membranes are bright red but may become cyanotic terminally. Venous blood is classically described as “cherry red” because of the presence of high venous blood pO₂; however, this color rapidly changes after death. Serum ammonia and neutral and aromatic amino acids are typically increased. Cardiac arrhythmias are common due to myocardial histotoxic hypoxia. Death occurs during severe asphyxial convulsions. The heart may continue to beat for several minutes after struggling, and breathing stops. The

elimination half-life of cyanide in dogs is reported to be 19 hr, so prognosis of recovery without therapeutic intervention is grave: it would take more than 4 days to eliminate >95% of the cyanide present.

Chronic cyanide poisoning: Chronic cyanogenic glycoside hypothyroidism will present as hypothyroidism with or without goiter. Cystitis ataxia toxidromes are typically associated with posterior ataxia or incoordination that may progress to irreversible flaccid paralysis, cystitis secondary to urinary incontinence, and hindlimb urine scalding and alopecia. Death, although uncommon, is often associated with pyelonephritis. Late-term abortion and musculoskeletal teratogenesis may also occur.

Lesions: *Acute cyanide poisoning:*

Necropsy personnel may require appropriate personal protective equipment, including respirators with suitable cartridges. Venous blood is classically described as being "bright cherry red"; however, this color rapidly fades after death or if the blood is exposed to the atmosphere. Whole blood clotting may be slow or not occur. Mucous membranes may also be pink initially, then become cyanotic after respiration ceases. The rumen may be distended with gas; in some cases the odor of "bitter almonds" may be detected after opening. Rumen contents may provide a positive sodium picrate paper test (or positive results on other rapid cyanide test strip systems). Rumen gases may provide positive results in cyanide Draeger tube rapid test systems. Agonal hemorrhages of the heart may be seen. Liver, serosal surfaces, tracheal mucosa, and lungs may be congested or hemorrhagic; some froth may be seen in respiratory passages. Cyanide also binds to iron (both Fe^{2+} and Fe^{3+}) present in myoglobin (although this occurs more slowly than the binding to cytochrome c oxidase and, hence, is not protective); this may result in a generalized dark coloration of skeletal muscle. Neither gross nor histologic lesions are consistently seen.

Multiple foci of degeneration or necrosis may be seen in the CNS of dogs chronically exposed to sublethal amounts of cyanide. These lesions have not been reported in livestock.

Chronic cyanide poisoning: Goiter may be present. Cystitis ataxia toxidromes are characterized by opportunistic bacterial cystitis with or without pyelonephritis and diffuse nerve fiber degeneration in the lateral and ventral funiculi of the spinal cord and brain stem. Hindlimb urine scalding and alopecia may be present.

Diagnosis: Appropriate history, clinical signs, postmortem findings, and demonstration of HCN in rumen (stomach) contents or other diagnostic specimens support a diagnosis of cyanide poisoning. Veterinarians should be aware of the possible need to use appropriate personal protective equipment, including a respirator, when collecting samples that may liberate cyanide gas (eg, rumen contents and rumen gas cap). A rapid qualitative and presumptive diagnosis can be made by testing representative plant samples or stomach contents using the picric acid paper test or by collecting rumen gas cap samples by trocarization and testing with a Draeger cyanide gas detection tube or other cyanide gas detection system. Negative results with such rapid presumptive tests do not completely exclude the possibility of cyanide poisoning. Suitable specimens for more sophisticated testing include the suspected food source, rumen/stomach contents, samples of the rumen gas cap, heparinized whole blood, liver, and muscle. Antemortem whole blood is preferred; other specimens should be collected as soon as possible after death, preferably within 4 hr. Specimens should be sealed in an airtight container, refrigerated or frozen, and submitted to the laboratory without delay. When cold storage is unavailable, immersion of specimens in 1%-3% mercuric chloride has been satisfactory. The rationale for using liver as a diagnostic sample is that cyanide binds to the Fe^{3+} form of cytochrome p450 and other heme-containing metabolic enzymes. The rationale for using skeletal muscle is that cyanide will bind to the iron moiety in myoglobin.

Where available, measurement of the urinary metabolite of cyanide, thiocyanate, may reveal increased concentrations after cyanide poisoning.

Hay, green chop, silage, or growing plants containing >220 ppm cyanide as HCN on a wet-weight (as is) basis are very dangerous as animal feed. Forage containing <100 ppm HCN, wet weight, is usually safe to pasture. Analyses performed on a dry-weight basis have the following criteria: >750 ppm HCN is hazardous, 500–750 ppm HCN is doubtful, and <500 ppm HCN is considered safe.

Normally expected cyanide concentrations in blood of most animal species are usually <0.5 mcg/mL. Minimal lethal blood concentrations are ~3 mcg/mL or less. Cyanide concentrations in muscle are similar to those in blood, but concentrations in liver are generally lower than those in blood. In dogs, whole blood cyanide concentrations may be 4–5 times greater than serum

concentrations because of binding to ferric ions and sequestration in RBCs.

Differential diagnoses include poisonings by nitrate or nitrite, urea, organophosphate, carbamate, chlorinated hydrocarbon pesticides, and toxic gases (carbon monoxide and hydrogen sulfide), as well as infectious or noninfectious diseases and other toxidromes that cause sudden death.

Treatment, Control, and Prevention:

Immediate treatment is necessary. The goal of treatment is to break the cyanide-cytochrome oxidase bond and reestablish the mitochondrial electron transport chain. One way to accomplish this is by using Fe^{3+} in hemoglobin (ie, inducing methemoglobinemia), which then acts as a high-affinity decoy chemical receptor for cyanide and forms cyanmethemoglobin. Classically, various nitrites have been used for this purpose; eg, inhaled amyl nitrite followed by IV injection of a nitrite salt (typically sodium nitrite) has been used to rapidly induce methemoglobinemia. Cyanide bound to methemoglobin can then be detoxified by rhodanese to thiocyanate. Because the rhodanese-mediated detoxification of cyanide to thiocyanate is usually capacity and rate limited by the availability of sulfur donors, treatment with nitrites is usually followed up by injection of sodium thiosulfate. Oral dosing with sodium thiosulfate into the rumen and/or stomach has also been suggested because the reaction between thiosulfate and cyanide can also occur nonenzymatically, and this may reduce any ongoing production of cyanide in the rumen/stomach environments.

If possible, the contents of one 0.3-mL vial of amyl nitrite should be inhaled by the animal as soon as possible after exposure, followed by an IV infusion of sodium nitrite (10 g/100 mL of distilled water or isotonic saline; 20 mg/kg body wt) over 3–4 min. Nitrite treatment is then followed by a slow IV injection of sodium thiosulfate (20% w/w) at ≥ 500 mg/kg. Thiosulfate is generally well tolerated; however, vomiting and hypotension can occur. The thiosulfate injection can be repeated if necessary. Oral administration of thiosulfate can also be considered in an attempt to convert any cyanide in the stomach/rumen into thiocyanate. Sodium nitrite therapy may be carefully repeated at 10 mg/kg, every 2–4 hr or as needed. Ideally, decisions regarding repeated treatment with nitrites should consider the degree of methemoglobinemia present.

Notably, thiosulfate treatment alone has been successful in some cases. However, thiosulfate treatment should ideally be

preceded by nitrite induction of methemoglobinemia in cases of confirmed cyanide poisoning. However, because thiosulfate is generally well tolerated, it is often administered alone in situations when cyanide exposure is likely but unconfirmed (eg, smoke inhalation or exposure to fires).

Hydroxocobalamin (vitamin B_{12a}) is also used as a cyanide antidote. Hydroxocobalamin detoxifies cyanide by binding to it and forming cyanocobalamin (ie, another decoy receptor approach), which is then excreted in urine. It has the advantages that it is relatively well tolerated, does not compromise blood oxygen-carrying capacity, and does not produce hypotension. Hydroxocobalamin does produce chromaturia (which may result in false urinalysis results), as well as infusion site reactions, GI upset, pruritus, and dysphagia. The suggested dosage is 70 mg/kg, infused IV over 15 min, repeated as necessary.

Sulfanegen (as the sodium or triethanolamine salt) has been developed for treatment of cyanide mass poisoning incidents. This approach has the advantage that sulfanegen is water soluble and can be administered IM. Sulfanegen is a prodrug that generates 3-mercaptopyruvic acid (3-MP), an intermediate in cysteine metabolism, which again acts as a decoy receptor for cyanide. By itself, the half-life of 3-MP is too short to be effective against cyanide poisoning. For this reason, prodrugs such as sulfanegen have been developed to increase the duration of action of 3-MP *in vivo*.

Alternative inducers of methemoglobinemia such as 4-dimethyl-aminophenol (DMAP; IM at 5 mg/kg) or hydroxylamine hydrochloride (IM at 50 mg/kg) have been suggested, because they produce methemoglobinemia more quickly than the nitrites currently in use. However, these hemoglobin-oxidizing agents are also relatively toxic to RBCs and can induce severe effects such as hemolysis and renal damage. These "rapid agents" still have the disadvantage of reducing blood oxygen-carrying capacity.

Other alternative antidotes in clinical development and use worldwide include dicobalt-ethylenediaminetetraacetic acid (EDTA) and α -ketoglutaric acid. Although hydroxycobalamin has been approved by the FDA for use in the USA, none of the others is readily available. Dicobalt-EDTA releases cobalt ions that react with cyanide ions; highly stable cyanide-cobalt complexes are then excreted by the kidneys. This drug is very potent and has immediate action but is reported to have numerous, severe adverse effects in people. The investigational antidote α -ketoglutaric acid

has a molecular configuration that renders it amenable to nucleophilic binding of cyanide without generation of methemoglobin. Pretreatment with this drug reduced lethal outcomes and increased efficacy of sodium thiosulfate, but postexposure efficacy in animals is unknown.

Sodium thiosulfate alone is also an effective antidotal therapy at ≥ 500 mg/kg, IV, plus 30 g/cow, PO, to detoxify any remaining HCN in the rumen. When available, oxygen should be used to supplement nitrite or thiosulfate therapy, especially in small animals. Hyperbaric oxygen therapy (100% oxygen breathed intermittently at a pressure > 1 atmosphere absolute) causes an above-normal partial pressure of oxygen (PO_2) in arterial blood and markedly increases the amount of oxygen dissolved in plasma. Oxygen-dependent cellular metabolic processes benefit from heightened oxygen tension in capillaries and enhanced oxygen diffusion from capillaries to critical tissues. Activated charcoal does not effectively absorb cyanide and thus is not recommended PO for antidotal therapy.

Caution is indicated in treatment. All cyanide antidotes are toxic by themselves. Many clinical signs of nitrate and prussic acid poisoning are similar, and injecting sodium nitrite induces methemoglobinemia identical to that produced by nitrite poisoning. If in doubt of the diagnosis, methylene blue, IV, at 4–22 mg/kg, may be used to induce methemoglobin. Because methylene blue can serve as both a donor and acceptor of electrons, it can reduce methemoglobin in the presence of excess methemoglobin or induce methemoglobin when only hemoglobin is present (but sodium nitrate is the more effective treatment for cyanide poisoning if the diagnosis is certain).

The best preventive step is to test suspect feed and/or pastures before allowing consumption. Pasture and forage sorghums (eg, Sudan grass and sorghum-Sudan grass hybrids) should not be grazed until they are > 60 cm tall or have been proved by testing to

have acceptable cyanide levels, to reduce danger from prussic acid poisoning. Animals should be fed before first turning out to pasture; hungry animals may consume forage too rapidly to detoxify HCN released in the rumen. Animals should be turned out to new pasture later in the day; potential for prussic acid release is reported to be highest during early morning hours. Free-choice salt and mineral with added sulfur may help protect against prussic acid toxicity. Grazing should be monitored closely during periods of environmental stress, eg, drought or frost. Abundant regrowth of sorghum can be dangerous; these shoots should be frozen and wilted before grazing.

Green chop forces livestock to eat both stems and leaves, thereby reducing problems caused by selective grazing. Cutting height can be raised to minimize inclusion of regrowth.

Sorghum hay and silage usually lose $\geq 50\%$ of prussic acid content during curing and ensiling processes. Free cyanide is released by enzyme activity and escapes as a gas. Although a rare occurrence, hazardous concentrations of prussic acid may still remain in the final product, especially if the forage had an extremely high cyanide content before cutting. Hay has been dried at oven temperatures for up to 4 days with no significant loss of cyanide potential. These feeds should be analyzed before use whenever high prussic acid concentrations are suspected. Potentially toxic feed should be diluted or mixed with grain or forage that is low in prussic acid content to achieve safe concentrations in the final product. At least in theory, the risk of chronic cyanide poisoning syndromes may be reduced by iodine supplementation in the case of hypothyroidism and by sulfur-containing amino acids in the case of chronic neurologic toxidromes. Great care must be taken when providing supplemental elemental sulfur sources in ruminants because of the possible risk of polioencephalomalacia (see p 1281).

FOOD HAZARDS

AVOCADO

Ingestion of avocado (*Persea americana*) has been associated with myocardial necrosis in mammals and birds and with sterile mastitis in lactating mammals. Cattle,

goats, horses, mice, rabbits, guinea pigs, rats, sheep, budgerigars, canaries, cockatiels, ostriches, chickens, turkeys, and fish are susceptible. Caged birds appear more sensitive to the effects of avocado, while chickens and turkeys appear more

resistant. Although an old case report exists of two dogs developing myocardial damage after avocado ingestion, dogs appear to be relatively resistant compared with other species.

Etiology: Ingestion of fruit, leaves, stems, and seeds of avocado has been associated with toxicosis in animals; leaves are the most toxic part. The Guatemalan varieties of avocado have been most commonly associated with toxicosis.

When purified, the toxic principle in avocado, persin, causes mastitis in lactating mice at 60–100 mg/kg, and dosages >100 mg/kg result in myocardial necrosis. Goats develop severe mastitis when ingesting 20 g of leaves/kg, whereas 30 g of leaves/kg results in cardiac injury. Acute cardiac failure developed in sheep fed avocado leaves at 25 g/kg for 5 days; 5.5 g/kg of leaves fed for 21 days or 2.5 g/kg for 32 days caused chronic cardiac insufficiency. Budgerigars fed 1 g of avocado fruit developed agitation and feather pulling, while 8.7 g of mashed avocado fruit resulted in death within 48 hr. Myocardial injury, mastitis, and colic have been reported in horses ingesting avocado fruit and/or leaves.

Pathogenesis: Avocado causes necrosis and hemorrhage of mammary gland epithelium of lactating mammals and myocardial necrosis in birds and mammals. Persin isolated from avocado leaves has caused lesions similar to those reported in natural cases.

Clinical Findings: In lactating animals, sterile mastitis occurs within 24 hr of exposure to avocado, accompanied by a 75% decrease in milk production. Affected mammary glands are firm, swollen, and produce watery, curdled milk. Lactation may provide a degree of protection against myocardial injury when avocado is ingested at lower doses. In nonlactating mammals, or at higher doses, myocardial insufficiency may develop within 24–48 hr of ingestion and is characterized by lethargy, respiratory distress, subcutaneous edema, cyanosis, cough, exercise intolerance, and death. Horses may develop edema of the head, tongue, and brisket. Birds develop lethargy, dyspnea, anorexia, subcutaneous edema of the neck and pectoral regions, and may die.

Lesions: Mammary glands are edematous and reddened, with watery, curdled milk. In animals with cardiac insufficiency, there is congestion of lungs and liver, often with dependent subcutaneous edema. There may be pulmonary edema and free fluid within

the abdominal cavity, pericardial sac, and thoracic cavity. The heart may contain pale streaks. Histopathologic lesions in the mammary gland include degeneration and necrosis of secretory epithelium, with interstitial edema and hemorrhage. Myocardial lesions include degeneration and necrosis of myocardial fibers, which are most pronounced in ventricular walls and septum; interstitial hemorrhage and/or edema may be present. In horses, symmetric ischemic myopathy of the head muscles and tongue, as well as ischemic myelomalacia of the lumbar spinal cord, have been described.

Diagnosis: Diagnosis of avocado toxicosis relies on history of exposure and clinical signs. There are no readily available specific tests that will confirm diagnosis. Differential diagnoses include other causes of mastitis (eg, infectious) and other myocardial disorders, including ionophore toxicosis, yew toxicosis, vitamin E/selenium deficiency, gossypol, cardiac glycoside toxicosis (eg, oleander), cardiomyopathy, and infectious myocarditis.

Treatment: NSAIDs and analgesics may benefit animals with mastitis. Treatment for congestive heart failure (eg, diuretics, antiarrhythmic drugs) may be of benefit but may not be economically feasible in livestock.

BREAD DOUGH

Raw bread dough made with yeast poses mechanical and biochemical hazards when ingested, including gastric distention, metabolic acidosis, and CNS depression. Although any species is susceptible, dogs are most commonly involved because of their indiscriminate eating habits.

Pathogenesis: The warm, moist environment of the stomach serves as an efficient incubator for the replication of yeast within the dough. The expanding dough mass causes the stomach to distend, resulting in vascular compromise to the gastric wall similar to that seen in gastric dilatation/volvulus. With sufficient gastric distention, respiratory compromise occurs. Yeast fermentation products include ethanol, which is absorbed into the bloodstream, resulting in inebriation and metabolic acidosis.

Clinical Findings: Early clinical signs may include unproductive attempts at emesis, abdominal distention, and

depression. As ethanol intoxication develops, the animal becomes ataxic and disoriented. Eventually, profound CNS depression, weakness, recumbency, coma, hypothermia, or seizures may be seen. Death is usually due to the effects of the alcohol rather than from gastric distention; however, the potential for dough to trigger gastric dilatation/volvulus in susceptible dog breeds should not be overlooked.

Diagnosis: A presumptive diagnosis can be based on history of exposure and clinical signs. Blood ethanol levels are consistently increased in cases of bread dough toxicosis. Differential diagnoses include gastric dilatation/volvulus, foreign body obstruction, ethylene glycol toxicosis, and ingestion of other CNS depressants (eg, benzodiazepines).

Treatment: With recent ingestions in asymptomatic animals, emesis may be attempted, although the glutinous nature of bread dough may make removal via emesis difficult. In animals in which emesis (whether induced or spontaneous) has been unsuccessful, gastric lavage may be attempted. Cold water introduced into the stomach may slow the rate of yeast fermentation and aid in dough removal. In rare cases, surgical removal of the dough mass may be required. Animals presenting with signs of alcohol toxicosis should be stabilized and any life-threatening conditions corrected before attempts to remove the dough are made. Alcohol toxicosis is managed by correcting acid-base abnormalities, managing cardiac arrhythmias as needed, and maintaining normal body temperature. Providing fluid diuresis to enhance alcohol elimination may be helpful. Anecdotally, yohimbine (0.1 mg/kg, IV) has been used to stimulate severely comatose dogs with alcohol toxicosis.

CHOCOLATE

Chocolate toxicosis may result in potentially life-threatening cardiac arrhythmias and CNS dysfunction. Chocolate poisoning occurs most commonly in dogs, although many species are susceptible. Contributing factors include indiscriminate eating habits and readily available sources of chocolate. Deaths have also been reported in livestock fed cocoa by-products and in animals consuming mulch from cocoa-bean hulls.

Etiology: Chocolate is derived from the roasted seeds of *Theobroma cacao*. The primary toxic principles in chocolate are the

methylxanthines theobromine (3,7-dimethylxanthine) and caffeine (1,3,7-trimethylxanthine). Although the concentration of theobromine in chocolate is 3–10 times that of caffeine, both constituents contribute to the clinical syndrome seen in chocolate toxicosis. The exact amount of methylxanthines in chocolate varies because of the natural variation of cocoa beans and variation within brands of chocolate products. However, in general, the total methylxanthine concentration of dry cocoa powder is ~800 mg/oz (28.5 mg/g), unsweetened (baker's) chocolate is ~450 mg/oz (16 mg/g), semisweet chocolate and sweet dark chocolate is ~150–160 mg/oz (5.4–5.7 mg/g), and milk chocolate is ~64 mg/oz (2.3 mg/g). Chocolate bars labeled as a percentage of cocoa/cacao are based on unsweetened chocolate, ie, a 65% cacao bar would contain ~293 mg (450 mg × 0.65) of methylxanthines per oz (10.4 mg/g). White chocolate is an insignificant source of methylxanthines. Cocoa bean hulls contain ~255 mg/oz (9.1 mg/g) methylxanthines.

The LD_{50} of both caffeine and theobromine is reportedly 100–200 mg/kg, but severe signs and deaths may occur at much lower dosages, and individual sensitivity to methylxanthines varies. In general, mild signs (vomiting, diarrhea, polydipsia) may be seen in dogs ingesting 20 mg/kg, cardiotoxic effects may be seen at 40–50 mg/kg, and seizures may occur at dosages ≥60 mg/kg. One ounce of milk chocolate per pound of body weight is a potentially lethal dose in dogs.

Pathogenesis: Theobromine and caffeine are readily absorbed from the GI tract and widely distributed throughout the body. They are metabolized in the liver and undergo enterohepatic recycling. Methylxanthines are excreted in the urine as both metabolites and unchanged parent compounds. The half-lives of theobromine and caffeine in dogs are 17.5 hr and 4.5 hr, respectively.

Theobromine and caffeine competitively inhibit cellular adenosine receptors, resulting in CNS stimulation, diuresis, and tachycardia. Methylxanthines also increase intracellular calcium levels by increasing cellular calcium entry and inhibiting intracellular sequestration of calcium by the sarcoplasmic reticulum of striated muscle. The net effect is increased strength and contractility of skeletal and cardiac muscle. Methylxanthines may also compete for benzodiazepine receptors within the CNS and inhibit phosphodiesterase, resulting in increased cyclic AMP

levels. Methylxanthines may also increase circulating levels of epinephrine and norepinephrine.

Clinical Findings: Clinical signs of chocolate toxicosis usually occur within 6–12 hr of ingestion. Initial signs may include polydipsia, vomiting, diarrhea, abdominal distention, and restlessness. Signs may progress to hyperactivity, polyuria, ataxia, rigidity, tremors, and seizures. Tachycardia, premature ventricular contractions, tachypnea, cyanosis, hypertension, hyperthermia, bradycardia, hypotension, or coma may occur. Hypokalemia may occur late in the course of the toxicosis, contributing to cardiac dysfunction. Death is generally due to cardiac arrhythmias, hyperthermia, or respiratory failure. The high fat content of chocolate products may trigger pancreatitis in susceptible animals.

Lesions: No specific lesions may be found in animals succumbing to chocolate toxicosis. Hyperemia, hemorrhages, or congestion of multiple organs may occur as agonal changes. Severe arrhythmias may result in pulmonary edema or congestion. Chocolate or cocoa bean hulls may be present in the GI tract at necropsy.

Diagnosis: Diagnosis is based on history of exposure, along with clinical signs. Amphetamine toxicosis, ma huang/guarana (ephedra/cafeine) toxicosis, pseudoephedrine toxicosis, cocaine toxicosis, and ingestion of antihistamines, antidepressants, or other CNS stimulants should be considered in the differential diagnosis.

Treatment: Stabilization of symptomatic animals is a priority in treating chocolate toxicosis. Methocarbamol (50–220 mg/kg, slow IV; no more than 330 mg/kg/day) or diazepam (0.5–2 mg/kg, slow IV) may be used for tremors and/or mild seizures; barbiturates may be required for severe seizures. Arrhythmias should be treated as needed: propranolol (0.02–0.06 mg/kg, slow IV) or metoprolol (0.2–0.4 mg/kg, slow IV) for tachyarrhythmias, atropine (0.01–0.02 mg/kg) for bradyarrhythmias, and lidocaine (1–2 mg/kg, IV, followed by 25–80 mg/kg/min infusion) for refractory ventricular tachyarrhythmias. Fluid diuresis may assist in stabilizing cardiovascular function and hastening urinary excretion of methylxanthines.

Once animals have stabilized, or in animals presenting before clinical signs have developed (eg, within 1 hr of ingestion), decontamination should be performed.

Induction of emesis using apomorphine or hydrogen peroxide should be initiated; in animals that have been sedated because of seizure activity, gastric lavage may be considered. Activated charcoal (1–4 g/kg, PO) should be administered; because of the enterohepatic recirculation of methylxanthines, repeated doses should be administered every 12 hr in symptomatic animals for as long as signs are present (control vomiting with metoclopramide, 0.2–0.4 mg/kg, SC or IM, qid as needed).

Other treatment for symptomatic animals includes maintaining thermoregulation, correcting acid-base and electrolyte abnormalities, monitoring cardiac status via electrocardiography, and placing a urinary catheter (methylxanthines and their metabolites can be reabsorbed across the bladder wall). Clinical signs may persist up to 72 hr in severe cases.

MACADAMIA NUTS

Ingestion of macadamia nuts by dogs has been associated with a nonfatal syndrome characterized by vomiting, ataxia, weakness, hyperthermia, and depression. Dogs are the only species in which signs have been reported.

Etiology: Macadamia nuts are cultivated from *Macadamia integrifolia* in the continental USA and *M. tetraphylla* in Hawaii and Australia. The mechanism of toxicity is not known. Dogs have shown signs after ingesting 2.4 g of nuts/kg body weight. Dogs experimentally dosed with commercially prepared macadamia nuts at 20 g/kg developed clinical signs within 12 hr and were clinically normal without treatment within 48 hr.

Clinical Findings: Within 12 hr of ingestion, dogs develop weakness, depression, vomiting, ataxia, tremors, and/or hyperthermia. Tremors may be secondary to muscle weakness. Macadamia nuts may be identified in vomitus or feces. Mild transient increases in serum triglycerides, lipases, and alkaline phosphatase were reported in some dogs experimentally dosed with macadamia nuts; these values quickly returned to baseline. Signs generally resolve within 12–48 hr.

Diagnosis: Diagnosis is based on history of exposure and clinical signs. Differential diagnoses include ethylene glycol toxicosis, ingestion of hypotensive agents, and infectious diseases (eg, viral enteritis).

Treatment: For asymptomatic dogs with recent ingestion of more than 1–2 g/kg, emesis should be induced; activated charcoal may be of benefit with large ingestions. Fortunately, most symptomatic dogs recover without any specific treatment. Severely affected dogs may be given supportive treatment such as fluids, analgesics, or antipruritics.

RAISINS AND GRAPES

Ingestion of grapes or raisins has resulted in development of anuric renal failure in some dogs. Cases reported to date have been in dogs; anecdotal reports exist of renal failure in cats and ferrets after ingestion of grapes or raisins. It is not known why many dogs can ingest grapes or raisins with impunity while others develop renal failure after ingestion. The condition has not been reproduced experimentally, although raisin extracts have been shown to cause damage to canine kidney cells in vitro.

Pathogenesis: The exact mechanism of toxicity is unknown, although the primary injury appears to be in the proximal renal tubular epithelium. Affected dogs develop anuric renal failure within 72 hr of ingestion of grapes or raisins. A clear dose-response relationship has not been determined, but as few as 4–5 grapes were implicated in the death of an 18-lb (8.2-kg) dog.

Clinical Findings: Most affected dogs develop vomiting and/or diarrhea within 6–12 hr of ingestion of grapes or raisins. ●ther signs include lethargy, anorexia, abdominal pain, weakness, dehydration, polydipsia, and tremors (shivering). Serum creatinine levels tend to rise early and disproportionately compared with serum urea nitrogen levels. ●liguric or anuric renal failure develops within 24–72 hr of exposure; once anuric renal failure develops, most dogs die or are euthanized. Transient increases in serum glucose, liver enzymes, pancreatic enzymes, serum calcium, or serum phosphorus develop in some dogs.

Diagnosis: Diagnosis is based on history of exposure, along with clinical signs. ●ther causes of renal failure (eg, ethylene glycol, cholecalciferol) should be considered in the differential diagnosis.

Treatment: Prompt decontamination of significant ingestion of grapes or raisins is recommended. Emesis may be induced

with 3% hydrogen peroxide (2 mL/kg; no more than 45 mL), followed by activated charcoal. With large ingestions or in cases in which vomiting and/or diarrhea has spontaneously developed within 12 hr of ingestion of grapes or raisins, aggressive fluid diuresis for a minimum of 48 hr is recommended. Renal function and fluid balance should be monitored during fluid administration. For oliguric dogs, urine production may be stimulated by using dopamine (0.5–3 mcg/kg/min, IV) and/or furosemide (2 mg/kg, IV). Anuric dogs are unlikely to survive unless peritoneal dialysis or hemodialysis is performed; even then, the prognosis is guarded.

XYLITOL

Xylitol is a sugar alcohol used to sweeten sugar-free products such as gums, candies, and baked goods. Ingestion of xylitol or xylitol-containing products by dogs has resulted in development of hypoglycemia and, less commonly, hepatic injury and/or failure. Dogs are the only species in which xylitol toxicosis has been reported.

Pathogenesis: In most mammals, xylitol has no significant effect on insulin levels, but in dogs, xylitol stimulates a rapid, dose-dependent insulin release that can result in profound hypoglycemia. Dosages of xylitol over ~75–100 mg/kg (34–45 mg/lb) have been associated with hypoglycemia in dogs. Some dogs ingesting xylitol at dosages >500 mg/kg (227 mg/lb) may develop severe hepatic insufficiency or failure, the mechanism of which is unknown.

Clinical Findings: Signs of hypoglycemia can develop within 30 min of ingestion or may be delayed up to 12–18 hr if the xylitol is in a substrate that slows its absorption (eg, some gum products). Clinical signs of hypoglycemia include vomiting, weakness, ataxia, depression, hypokalemia, seizures, and coma. Signs of liver injury may not occur until ≥24–48 hr after ingestion of xylitol, although increases in liver enzymes are often detectable within 8–12 hr of ingestion. Clinical signs of liver injury include depression, vomiting, icterus, and coagulopathy; other findings include hyperbilirubinemia, thrombocytopenia, and hyperphosphatemia. Hyperphosphatemia is considered a poor prognostic indicator, because it was present in 4 of 5 dogs that died of liver failure after xylitol ingestion (phosphorus was not measured in the fifth dog). Not all dogs that develop xylitol-induced liver injury develop hypoglycemia.

Diagnosis: Diagnosis is based on clinical findings and history of exposure. Other causes of hypoglycemia include hypoglycemic drugs, juvenile hypoglycemia, hunting dog hypoglycemia, insulinoma, and parenteral insulin overdose. Differential diagnoses for liver insufficiency include infectious (eg, leptospirosis, viral hepatitis), environmental (eg, heat stroke, trauma), and toxic (eg, iron, acetaminophen, mushroom, blue-green algae, cycad palms) causes. Lesions of dogs succumbing to liver injury have included hepatic necrosis with loss of normal hepatic architecture.

Treatment: Because of the potential for rapid onset of clinical signs of hypoglycemia, emesis should ideally be attempted only under veterinary supervision and in asymptomatic animals. Activated charcoal does not appreciably bind xylitol and is not recommended. If >75 – 100 mg/kg (227 mg/lb) of xylitol has been ingested, animals should be hospitalized and baseline blood glucose values measured; dogs ingesting >500 mg/kg (227 mg/lb) of xylitol should have baseline liver values measured. Blood glucose

should be monitored every 1–2 hr for at least 12 hr, while liver values should be evaluated every 24 hr for at least 72 hr. If hypoglycemia develops, it should be managed with dextrose IV boluses and/or constant-rate infusions. Hypoglycemia may persist as long as 24 hr or more, so treatment should be continued until the dog can maintain a normal blood glucose level without supplemental dextrose. Dextrose should be administered to dogs ingesting xylitol at >500 mg/kg (227 mg/lb), even though normoglycemic, and hepatoprotectants such as *N*-acetylcysteine, *S*-adenosylmethionine, and silymarin should be considered. Treatment of coagulopathy or other manifestations of liver insufficiency should be performed as needed. The prognosis for uncomplicated hypoglycemia is good, if prompt treatment is obtained. Mild increases in liver enzyme usually resolve within a few days. Severe increases in liver enzymes and/or signs of liver insufficiency indicate a more guarded prognosis; in one study, 62.5% of dogs with signs of liver injury died or were euthanized despite aggressive veterinary intervention.

HERBICIDE POISONING

Herbicides are used routinely to control noxious plants. Most of these chemicals, particularly the more recently developed synthetic organic herbicides, are quite selective for specific plants and have low toxicity for mammals; other, less-selective compounds (eg, sodium arsenite, arsenic trioxide, sodium chlorate, ammonium sulfamate, borax, and many others) were formerly used on a large scale and are more toxic to animals.

Vegetation treated with herbicides at proper rates normally will not be hazardous to animals, including people. Particularly after the herbicides have dried on the vegetation, only small amounts can be dislodged. When herbicide applications have been excessive, damage to lawns, crops, or other foliage is often evident.

The residue potential for most of these agents is low. However, runoff from agricultural applications and entrance into drinking water cannot be excluded. The possibility of residues should be explored if significant exposure of food-producing

animals occurs. The time recommended before treated vegetation is grazed or used as animal feed is available for a number of products.

Most health problems in animals result from exposure to excessive quantities of herbicides because of improper or careless use or disposal of containers. When herbicides are used properly, poisoning problems in veterinary practice are rare. With few exceptions, it is only when animals gain direct access to the product that acute poisoning occurs. Acute signs usually will not lead to a diagnosis, although acute GI signs are frequent. All common differential diagnoses should be excluded in animals showing signs of a sudden onset of disease or sudden death. The case history is critical. Sickness after feeding, spraying of pastures or crops adjacent to pastures, a change in housing, or direct exposure may lead to a tentative diagnosis of herbicide poisoning. Generally, the nature of exposure is hard to identify because of storage of herbicides in mis- or unlabeled containers. Unidentified

spillage of liquid from containers or powder from torn or damaged bags near a feed source, or visual confusion with a dietary ingredient or supplement, may cause the exposure. Once a putative chemical source has been identified, an animal poison control center should be contacted for information on treatments, laboratory tests, and likely outcome.

Chronic disease caused by herbicides is even more difficult to diagnose. It may include a history of herbicide use in proximity to the animals or animal feed or water source, or a gradual change in the animals' performance or behavior over a period of weeks, months, or even years. Occasionally, it involves manufacture or storage of herbicides nearby. Samples of possible sources (ie, contaminated feed and water) for residue analysis, as well as tissues from exposed animals taken at necropsy, are essential. Months or even years may be required to successfully identify a problem of chronic exposure.

To recognize whether an animal has been exposed to herbicides or accidental poisoning, standardized analytical procedures for diagnostic investigation of biologic materials have become established and are

subsumed under the term "biomonitoring." Accurate biomonitoring is an important tool to evaluate human or animal exposure to such herbicides by measuring the levels of these chemicals, their metabolites, or altered biologic structures or functions in biologic materials such as urine, blood or blood components, exhaled air, hair or nails, and tissues. The use of urine is advantageous because of ready availability. As such, urine has been used for biomonitoring of several herbicides, including 2,4-D, 2,4,5-T, MCPA (2-methyl-4-chlorophenoxyacetic acid), atrazine, diuron, alachlor, metolachlor, paraquat, diquat, imazapyr, imazapic, imazethapyr, imazamox, imazaquin, and imazamethabenz-methyl herbicides, with the objective to assess exposure and health risk to exposed animals.

If poisoning is suspected, the first step in management is to halt further exposure. Animals should be separated from any possible source before attempting to stabilize and support them. If there are life-threatening signs, efforts to stabilize animals by general mitigation methods should be started. Specific antidotal treatments, when available, may help to confirm the diagnosis. As time permits, a

TABLE 1 HERBICIDE POISONING

Compound	Acute Oral LD ₅₀ —Rat	NOAEL ^a (oral)	Acute Dermal LD ₅₀
Acetochlor	2,148–2,950 mg/kg	Dog, 1 yr 12 mg/kg/day	Rabbit 4,166 mg/kg
Acifluorfen	1,300 mg/kg (F)	Rat, 2 yr 180 ppm	Rabbit >2,000 mg/kg
Acrolein	29 mg/kg	Rat, 13 wk 150 mg/L in drinking water	Rabbit 231 mg/kg
Alachlor	930–1,200 mg/kg	Dog, 90 days <200 mg/kg/day	Rabbit 13,300 mg/kg
Ametryn	1,009–1,405 mg/kg	Rat reproduction, 50 ppm	Rabbit 2,020 mg/kg
α-Metolachlor	2,675–2,952 mg/kg	Dog, 90 days 0.0125 mg/kg/day	Rat 2,020 mg/kg

more detailed history and investigation should be completed. The owner should be made aware of the need for full disclosure of facts to successfully determine the source of poisoning, eg, unapproved use or failure to properly store a chemical.

Toxicity and Management of Poisoning

There are >200 active ingredients used as herbicides; however, some of them are believed to be obsolete or no longer in use. Of these, several have been evaluated for their toxic potential and are discussed below. More specific information is available on the label and from the manufacturer, cooperative extension service, or poison control center. Selected information on herbicides, such as the acute oral toxic dose (LD_{50}) in rats, the amount an animal can be exposed to without being affected (no adverse effect level), the likelihood of problems caused by dermal contact in rabbits (dermal LD_{50} , eye and skin irritation), deleterious effects on avian species, and toxicity to fish in water, is included for some commonly used

herbicides (see TABLE 1). Comparative toxic doses (TD) and lethal doses (LD) of selected herbicides in domesticated species, such as monkeys, cattle, sheep, pigs, cats, dogs, and chickens, is also summarized (see TABLE 2). The information is only a guideline, because the toxicity of herbicides may be altered by the presence of other ingredients (eg, impurities, surfactants, stabilizers, emulsifiers) present in the compound. With a few exceptions, most of the newly developed chemicals have a low order of toxicity to mammals. However, some herbicides, such as atrazine, buturon, butiphos, chloridazon, chlorpropham, cynazine, 2,4-D and 2,4,5-T alone or in combination, dichlorprop, dinoseb, dinoterb, linuron, mecoprop, monolinuron, MCPA (2-methyl-4-chlorophenoxyacetic acid), prometryn, propachlor, nitrofen, silvex, TCDD (a common contaminant during manufacturing process of some herbicides such as 2,4-D and 2,4,5-T), and tridiphane, are known to have adverse effects on development of embryos and reproduction abnormalities in experimental animals. A list of such chemicals is summarized in TABLE 3.

TABLE 1 HERBICIDE POISONING (continued)

Avian Toxicity/NOAEC ^b	Toxicity to Fish in Water	Skin and Eye Irritation
LC ₅₀ 5 day Bobwhite quail and Mallard duck 5,620 mg/kg	LC ₅₀ 96 hr Rainbow trout 0.45 mg/L	Skin—mild Eye—mild
LC ₅₀ 8 day Mallard duck > 10,000 mg/kg	LC ₅₀ 96 hr Rainbow trout 31 mg/L	Skin—moderate Eye—severe
LD ₅₀ (oral) Bobwhite quail 19 mg/kg Mallard duck 9.1 mg/kg	LC ₅₀ 24 hr Bluegill and Rainbow trout 0.024 mg/L	Skin—severe Eye—severe
		Skin—mild
LD ₅₀ (oral) Birds >2,250 mg/kg LC ₅₀ 5 day Birds >5,620 ppm		Skin—irritation Guinea pig—dermal sensitization Eye—mild
LC ₅₀ 8 day Bobwhite quail and Mallard duck >10,000 ppm	LC ₅₀ 96 hr Bluegill and Rainbow trout 3.9–10 ppm	Skin—slight Eye—mild

^a Anorexia and weight loss reported. No deaths were reported in dogs at a tebuthiuron dosage of 500 mg/kg body wt.

INORGANIC HERBICIDES AND ORGANIC ARSENICALS

Substances such as inorganic arsenicals (sodium arsenite, arsenic trioxide), organic arsenicals (methyl arsonate, methyl arsonic acid), sodium chlorate, ammonium sulfamate, borax, and many others were formerly used on a large scale. These older herbicides are nonselective, generally cheaper, more toxic, and more likely to cause problems than newer compounds. Their use has been mostly curtailed in developed countries.

Arsenicals: The use of inorganic arsenicals as herbicides has been reduced greatly because of livestock losses, environmental persistence, and their carcinogenic potential. These compounds can be hazardous to animals when used as

recommended. Ruminants (including deer) are apparently attracted to and lick plants poisoned with arsenite.

The highly soluble organic arsenicals can concentrate in pools in toxic quantities after a rain has washed them from recently treated plants. Arsenicals are used as desiccants or defoliants on cotton, and residues of cotton harvest fed to cattle may contain toxic amounts of arsenic. Signs and lesions caused by organic arsenical herbicides resemble those of inorganic arsenical poisoning. Single toxic oral doses for cattle and sheep are 22–55 mg/kg. Poisoning may be expected from smaller doses if consumed on successive days.

Dimercaprol (3 mg/kg for large animals, and 2.5–5 mg/kg for small animals, IM, every 4–6 hr) is the recommended therapy. Sodium thiosulfate also has been used (20–30 g, PO, in ~300 mL of water for cattle; one-fourth this dose for sheep); however, a

TABLE 3 HERBICIDES WITH POTENTIAL TO CAUSE DEVELOPMENTAL TOXICITY IN EXPERIMENTAL ANIMALS

Compound	Effects
Atrazine	Disruption of ovarian cycle and induced repetitive pseudopregnancy (rats, at high doses)
Buturon	Cleft palate, increased fetal mortality (mice)
Butiphos	Teratogenic (rabbit)
Chloridazon	Malformations
Chlorpropham	Malformations or other developmental toxicity (mice)
Cynazine	Malformations such as cyclopia and diaphragmatic hernia (rabbits); skeletal variations in rats
2,4-D ^a or 2,4,5-T ^a alone or in combination	Malformations such as cleft palate, hydronephrosis; teratogenic (mice, rats)
Dichlorprop	Teratogenic (mice); affect postnatal behavior (rats)
Dinoseb ^b	Multiple defects (mice, rabbits)
Dinoterb	Skeletal malformations (rats); skeletal, jaw, head, and visceral (rabbits)
Linuron	Malformations (rats)
Mecoprop	Malformations (mice only)
Monolinuron	Cleft palate (mice)
MCPA ^c	Teratogenic and embryotoxic (rats), teratogenic (mice)
Prometryn	Head, limbs, and tail defects (rat)
Propachlor	Slightly teratogenic (rats)
Nitrofen ^b	Malformations (mice, rats, hamsters)
Silvex	Teratogenic (mice)
TCDD ^a	Malformations/teratogenic (fetotoxicity in chickens, rats, mice, rabbits, guinea pigs, hamsters, and monkeys)
Tridiphane	Malformations such as cleft palate (mice); skeletal variations (rats)

^a TCDD is a common contaminant during the manufacturing process of some herbicides such as 2,4-D and 2,4,5-T.

^b Obsolete

^c 2-methyl-4-chlorophenoxyacetic acid

rationale for its use is not established, and it may be unrewarding. (*See also* ARSENIC POISONING, p 3071.)

Ammonium Sulfamate: Ruminants apparently can metabolize ammonium

sulfamate to some extent and, in some studies, exposed animals made better gains than did control animals. However, sudden deaths have occurred in cattle and deer that consumed treated plants. Large doses (> 1.5 g/kg) induce ammonia poisoning in

ruminants. Treatment is designed to lower rumen pH by dilution with copious amounts of water to which weak acetic acid (vinegar) has been added.

Borax: Borax is toxic to animals if consumed in moderate to large doses (>0.5 g/kg). Poisoning has not been reported when borax was used properly but has occurred when it was accidentally added to livestock feed and when borax powder was scattered in the open for cockroach control. Principal signs of acute poisoning are diarrhea, rapid prostration, and perhaps convulsions. An effective antidote is not known. Balanced electrolyte fluid therapy with supportive care is indicated.

Sodium Chlorate: Many cases of chlorate poisoning of livestock have occurred both from ingestion of treated plants and from accidental consumption of feed to which it was mistakenly added as salt. Cattle sometimes are attracted to foliage treated with sodium chlorate. Considerable quantities must be consumed before signs of toxicity appear. The minimum lethal dose is 1.1 g/kg for cattle, 1.54–2.86 g/kg for sheep, and 5.06 g/kg for poultry. Ingestion results in hemolysis of RBCs and conversion of Hgb to methemoglobin. Treatment with methylene blue (10 mg/kg) must be repeated frequently because, unlike the nitrites, the chlorate ion is not inactivated during conversion of Hgb to methemoglobin and is capable of producing an unlimited quantity of methemoglobin as long as it is present in the body. Blood transfusions may reduce some of the tissue anoxia caused by methemoglobin; IV isotonic saline can hasten elimination of the chlorate ion. Mineral oil containing 1% sodium thiosulfate will inhibit further absorption of chlorate in monogastric animals.

ORGANIC HERBICIDES

Anilide, Acetamides, or Amide

Compounds: These herbicides (propanil, cypromid, clomiprop, bensulide, dimethenamid) are plant growth regulators, and some members of this group are more toxic than others. Hemolysis, methemoglobinemia, and immunotoxicity have occurred after experimental exposure to propanil. (For discussion of bensulide, *see* p 2997.)

Bipyridyl Compounds or Quaternary Ammonium Herbicides: The bipyridyl compounds (diquat, paraquat) produce toxic effects in the tissues of exposed animals by development of free radicals.

Tissues can be irritated after contact. For example, mouth lesions have been seen after contact with recently sprayed pastures. Skin irritation and corneal opacity occur on external exposure to these chemicals, and inhalation is dangerous. Animals, including people, have died as a result of drinking from contaminated containers.

Paraquat and diquat have somewhat different mechanisms of action. Diquat exerts most of its harmful effects in the GI tract. Animals drinking from an old diquat container showed anorexia, gastritis, GI distention, and severe loss of water into the lumen of the GI tract. Signs of renal impairment, CNS excitement, and convulsions occur in severely affected individuals. Lung lesions are uncommon.

Paraquat has a biphasic toxic action after ingestion. Immediate effects include excitement, convulsions or depression and incoordination, gastroenteritis with anorexia, and possibly renal involvement and respiratory difficulty. Eye, nasal, and skin irritation can be caused by direct contact, followed within days to 2 wk by pulmonary lesions as a result of lipid-membrane peroxidation and thus destruction of the type I alveolar pneumocytes. This is reflected in progressive respiratory distress and is evident on necropsy as pulmonary edema, hyaline membrane deposition, and alveolar fibrosis.

There is no specific treatment. Because these chemicals are absorbed slowly, intensive oral administration of adsorbents in large quantities and cathartics is advised. Bentonite or Fuller's earth is preferred, but activated charcoal will suffice. Toxicity of paraquat is enhanced by deficiency of vitamin E or selenium, oxygen, and low tissue activity of glutathione peroxidase. Therefore, vitamin E and selenium with supportive therapy may be useful in early stages of intoxication. Excretion may be accelerated by forced diuresis induced by mannitol and furosemide. Oxygen therapy and fluid therapy are contraindicated.

Carbamate and Thiocarbamate

Compounds: These herbicides (terbutylcarb, asulam, carboxazole, EPTC, pebulate, triallate, vernolate, butylate, thiobencarb) are moderately toxic; however, they are used at low concentrations, and poisoning problems would not be expected from normal use. Massive overdosage, as seen with accidental exposure, produces signs similar to those induced by the insecticide carbamates, with lack of appetite, depression, respiratory difficulty, mouth

watering, diarrhea, weakness, and seizures. Thiobencarb has induced toxic neuropathies in neonatal and adult laboratory rats. It appears to increase permeability of the blood-brain barrier. There is no suitable antidote. Supportive and symptomatic treatment is recommended.

Aromatic/Benzoic Acid Compounds:

The herbicides in this group (chloramben, dicamba, and naptalam) have a low order of toxicity to domestic animals, and poisoning after normal use has not been reported. Environmental persistence and toxicity to wildlife is also low. The signs and lesions are similar to those described for the phenoxy acid derivatives (*see below*). There is no suitable antidote. Supportive and symptomatic treatment is recommended.

Phenoxy Acid Derivatives: These acids and their salts and esters (2,4-D [2,4-dichlorophenoxyacetic acid], dalapon, dichloroprop [2,4-DP], 2,4,5-T [2,4,5-trichlorophenoxyacetic acid], 2,4-DB, MCPA, MCPB, mecoprop, and silvex) are commonly used to control undesirable plants. As a group, they are essentially nontoxic to animals, except silvex which is unusually very toxic. When large doses are fed experimentally, general depression, anorexia, weight loss, tenseness, and muscular weakness (particularly of the hindquarters) are noted. Large doses in cattle may interfere with rumen function. Dogs may develop myotonia, ataxia, posterior weakness, vomiting, diarrhea, and metabolic acidosis. The oral LD_{50} for 2,4-D and 2,4,5-T in dogs is 100–800 mg/kg. Even large doses, up to 2 g/kg, have not been shown to leave residues in the fat of animals. These compounds are plant growth regulators, and treatment may result in increased palatability of some poisonous plants as well as increased nitrate and cyanide content.

The use of 2,4,5-T was curtailed because extremely toxic contaminants, collectively called dioxins (TCDD and HCDD), were found in technical grade material (*see p 3056*). TCDD is considered carcinogenic, mutagenic, teratogenic, and fetotoxic, and is able to cause reproductive damage and other toxic effects. Although manufacturing methods have reduced the level of the contaminants, use of this herbicide is very limited worldwide.

Treatment is usually symptomatic and supportive. IV fluids should be given to promote diuresis. Adsorbents and drugs

that aid in restoration of liver function are recommended.

Dinitrophenolic Compounds: Several substituted dinitrophenols alone or as salts such as dinitrophenol, dinitrocresol, dinoseb, and binapacryl are highly toxic to all classes of animals (LD_{50} 20–100 mg/kg body wt). Poisoning can occur if animals are sprayed accidentally or have immediate access to forage that has been sprayed, because these compounds are readily absorbed through skin or lungs. Dinitrophenolic herbicides markedly increase oxygen consumption and deplete glycogen reserves. Clinical signs include fever, dyspnea, acidosis, tachycardia, and convulsions, followed by coma and death with a rapid onset of rigor mortis. Cataracts can occur in animals with chronic dinitrophenol intoxication. In cattle and other ruminants, methemoglobinemia, intravascular hemolysis, and hemoproteinemia have been seen. Exposure to these compounds may cause yellow staining of the skin, conjunctiva, or hair.

An effective antidote for dinitrophenol compounds is not known. Affected animals should be cooled and sedated to help control hyperthermia. Use of physical cooling measures (eg, cool baths or sponging and keeping the animal in a shaded area) are recommended. Atropine sulfate, aspirin, and antipyretics should not be used. Dextrose-saline infusions in combination with diuretics and tranquilizers such as diazepam (not barbiturates) are very useful. Phenothiazine tranquilizers are contraindicated. IV administration of large doses of sodium bicarbonate (in carnivores), parenteral vitamin A, and oxygen therapy may be useful. If the toxin was ingested and the animal is alert, emetics should be administered; if the animal is depressed, gastric lavage and treatment with activated charcoal should be performed.

In ruminants with methemoglobinemia, methylene blue solution (2%–4%, 10 mg/kg, IV, tid, during the first 24–48 hr) and ascorbic acid (5–10 mg/kg, IV) are useful.

Organophosphate Compounds:

Organophosphate compounds such as glyphosate, glufosinate, and bensulide are broad-spectrum, nonselective systemic herbicides. Glyphosate and glufosinate exist as free acids, but because of their slow solubility they are marketed as the isopropyl amine or trimethylsulfonium salts of glyphosate and the ammonium salt of

glufosinate. These are widely used herbicides with low toxicity. However, they are toxic to fish. Sprayed forage appears to be preferred by cattle for 5–7 days after application, but this causes little or no problem.

Dogs and cats show eye, skin, and upper respiratory tract signs when exposed during or subsequent to an application to weeds or grass. Nausea, vomiting, staggering, and hindleg weakness have been seen in dogs and cats exposed to fresh chemical on treated foliage. The signs usually disappear when exposure ceases, and minimal symptomatic treatment is needed. However, formulations of these compounds may lead to hemolysis and GI, cardiovascular, and CNS effects due to presence of the surfactant polyoxyethylenamine. Treatment should include washing the chemical off the skin, evacuating the stomach, and tranquilizing the animal. Massive exposure with acute signs due to accidental poisoning should be handled as an organophosphate poisoning (see p 3064).

Bensulide, listed as a plant growth regulator, has an oral LD_{50} in rats of 271–770 mg/kg; in dogs, the lethal dose is >200 mg/kg. The most prominent clinical sign is anorexia, but other signs are similar to those caused by 2,4-D poisoning.

Triazolopyrimidine Compounds:

Triazolopyrimidine herbicides include cloransulam-methyl, diclosulam, florasulam-methyl, flumetsulam, and metosulam. The acute oral toxicity is very low. There is no suitable antidote. Supportive and symptomatic treatment is recommended.

Ureas and Thiourea Compounds:

The ureas and thioureas (polyureas) are available under different names such as diuron, fluometuron, isoproturon, linuron, buturon, chlorbromuron, chlortoluron, chloroxuron, difenoxuron, fenuron, methiuron, metobromuron, metoxuron, monuron, neburon, parafluron, siduron, tebuthiuron, tetrafluron, and thidiazuron. Of these, diuron and fluometuron are the most commonly used in the USA, whereas isoproturon is mostly used in other countries. In general, these compounds have low acute toxicity and are unlikely to present any hazard in normal use, except tebuthiuron, which may be slightly hazardous. Cattle are more sensitive to polyurea herbicides than sheep, cats, and dogs.

Signs and lesions are similar to those described for the phenoxyacetic herbicides (see above). The substituted urea herbicides induce hepatic microsomal enzymes and may alter metabolism of other xenobiotic

agents. Altered calcium metabolism and bone morphology have been seen in laboratory animals. Recovery from diuron intoxication is quick (within 72 hr), and no signs of skin irritation or dermal sensitization have been reported in guinea pigs. After repeated administration, hemoglobin levels and RBC counts are significantly reduced, while methemoglobin concentration and WBC counts are increased. Increased pigmentation (hemosiderin) in the spleen is seen histopathologically. Linuron in sheep causes erythrocytosis and leukocytosis with hypohemoglobinemia and hypoproteinemia, hematuria, ataxia, enteritis, degeneration of the liver, and muscular dystrophy. In chickens, it leads to weight loss, dyspnea, cyanosis, and diarrhea. It is nontoxic to fish. Fluometuron is less toxic than diuron. In sheep, depression, salivation, grinding of teeth, chewing movements of the jaws, mydriasis, dyspnea, incoordination of movements, and drowsiness are commonly seen. On histopathology, severe congestion of the red pulp with corresponding atrophy of the white pulp of the spleen and depletion of the lymphocyte elements have been reported. The acute LD_{50} of isoproturon in rats is similar to that of diuron.

Polyurea herbicides have been suspected to have some mutagenic effects but do not have carcinogenic potential. In general, these compounds do not cause developmental and reproductive toxicity, except for monolinuron, linuron, and buturon, which are known to cause some teratogenic abnormalities in experimental animals. There is no suitable antidote. Supportive and symptomatic treatment is recommended.

Polycyclic Alkanoic Acids or Aryloxy-phenoxypropionic Compounds:

Members of this group (diclofop, fenoxaprop, fenthiaprop, fluzafop, haloxyfop) have moderately low toxicity (acute oral LD_{50} in rats 950 mg/kg to >4,000 mg/kg), except for haloxyfop-methyl (LD_{50} ~400 mg/kg). These compounds are more toxic if exposure is dermal. The dermal LD_{50} of diclofop in rabbits is only 180 mg/kg. There is no suitable antidote. Supportive and symptomatic treatment is recommended.

Triazinyl(sulfonyl)urea or Sulfonylurea Compounds:

Toxicity of this group of herbicides (chlorsulfuron, sulfometuron, ethametsulfuron, chloremuron) appears to be quite low. The oral acute LD_{50} in rats is in the range of 4,000–5,000 mg/kg. The dermal acute LD_{50} in rabbits is ~2,000 mg/kg. There is no suitable antidote. Supportive and symptomatic treatment is recommended.

Triazines and Triazoles: Triazines and triazoles have been used extensively as selective herbicides. These herbicides are inhibitors of photosynthesis and include both the asymmetric and symmetric triazines. Examples of symmetric triazines are chlorotriazines (simazine, atrazine, propazine, and cyanazine), the thiomethyl-s-triazines (ametryn, prometryn, terbutryn), and methoxy-s-triazine (prometon). The commonly used asymmetric triazine is metribuzin.

These herbicides have low oral toxicity and are unlikely to pose acute hazards in normal use, except ametryn and metribuzin, which may be slightly to moderately hazardous. They do not irritate the skin or eyes and are not skin sensitizers. The exceptions are atrazine, which is a skin sensitizer, and cyanazine, which is toxic by the oral route. Sensitivity of sheep and cattle to these herbicides is appreciably high. The main signs are anorexia, hemotoxicity, hypothermia, locomotor disturbances, irritability, tachypnea, and hypersensitivity. Simazine is excreted in milk, so it is of public health concern. Atrazine is more toxic to rats but comparatively less toxic to sheep and cattle than simazine. When cultured human cells are exposed to atrazine, splenocytes are damaged; bone marrow cells are not affected. Atrazine induces liver microsomal enzymes and is converted to *N*-dealkylated derivatives. In contrast to simazine, it is not excreted in milk. There is no suitable antidote. Supportive and symptomatic treatment is recommended.

Protoporphyrinogen Oxidase

Inhibitors: Protox inhibitors may be diphenyl ether (DPE) or non-diphenyl ether (non-DPE) such as nitrofen and oxadiazon. In the past few years, numerous other non-oxygen-bridged compounds (non-DPE protox inhibitors) with the same site of action (carfentrazone, JV 485, and oxadiargyl) have been marketed. Protox inhibitors have little acute toxicity and are unlikely to pose an acute hazard in normal use. These compounds increase porphyrin levels in animals when administered orally; the porphyrin levels return to normal within a few days. There is no suitable antidote. Supportive and symptomatic treatment is recommended.

Substituted Anilines: The most commonly used herbicides of this group are alachlor, acetochlor, butachlor, metolachlor,

and propachlor. Low doses in rats and dogs do not produce any adverse effects, but longterm exposure in dogs causes liver toxicity and affects the spleen. Ocular lesions produced by alachlor are considered to be unique to the Long-Evans rat, because the response has not been seen in other strains of rats or in mice or dogs.

Compared with other substituted anilines, propachlor is severely irritating to the eye and slightly irritating to the skin. Propachlor produces skin sensitization in guinea pigs. High doses of propachlor produce erosion, ulceration, and hyperplasia of the mucosa and herniated mucosal glands in the pyloric region of stomach and hypertrophy and necrosis of the liver in rats. In dogs, there is poor diet palatability, which results in poor feed consumption and weight loss. There is no suitable antidote. Supportive and symptomatic treatment is recommended.

Imidazolinones: Imidazolinone herbicides include imazapyr, imazamethabenz-methyl, imazapic, imazethapyr, imazamox, and imazaquin. These are selective broad-spectrum herbicides. Imidazolinone herbicides caused slight to moderate skeletal myopathy and/or slight anemia in dogs during 1-yr dietary toxicity studies with three structurally similar imidazolinones (imazapic, imazaquin, and imazethapyr). There is no evidence of any adverse effect on reproductive performance or of fetal abnormalities in rats or rabbits. There is no suitable antidote. Supportive and symptomatic treatment is recommended.

Other Herbicides: Bromacil and terbacil are commonly used methyluracil compounds. Toxic doses of bromacil can be hazardous, especially for sheep, but no field case of toxicity has been reported. The nitrile herbicides, ioxynil and bromoxynil, may uncouple and/or inhibit oxidative phosphorylation. Ioxynil, presumably because of its iodine content, causes enlargement of the thyroid gland in rats.

A number of substances are used as defoliants in agriculture. For example, sulfuric acid is used to destroy potato haulms and two closely related trialkylphosphorothioates (DEF and merphos) to defoliate cotton. A notable feature of the latter is that it produces organophosphate-induced delayed neuropathy in hens. Chlomequat is used as a growth regulator on fruit trees. The signs of toxicity in experimental animals indicate that it is a partial cholinergic agonist.

HOUSEHOLD HAZARDS

See also RODENTICIDE POISONING, p 3165; TOXICITIES FROM HUMAN DRUGS, p 3024; POISONOUS PLANTS, p 3103; and FOOD HAZARDS, p 2964.

Household chemicals (eg, products containing alcohols, bleaches, or corrosives) found in the home represent a risk of toxicosis if companion animals are exposed to concentrates or undiluted products, but casual exposure to areas in which these compounds have been used appropriately rarely causes any serious problems.

ALCOHOLS

Alcohol toxicosis results in metabolic acidosis, hypothermia, and CNS depression. All species are susceptible.

Etiology: Ethanol, methanol, and isopropanol are the alcohols most frequently associated with toxicosis in companion animals. Ethanol is present in a variety of alcoholic beverages, some rubbing alcohols, drug elixirs, and fermenting bread dough (*see* p 2965). Methanol is most commonly found in windshield washer fluids (windshield “antifreeze”). The lethal oral dose of methanol in dogs is 4–8 mL/kg, although significant clinical signs may be seen at lower dosages. Isopropanol is twice as toxic as ethanol and is found in rubbing alcohols and in alcohol-based flea sprays for pets. Oral dosages of isopropanol ≥ 0.5 mL/kg may result in significant clinical signs in dogs.

Pathogenesis: All alcohols are rapidly absorbed via the GI tract and most are well absorbed dermally; toxicosis from overspraying pets with alcohol-based flea sprays is not uncommon. Alcohols reach peak plasma levels within 1.5–2 hr and are widely distributed throughout the body. They are metabolized in the liver to acetaldehyde (ethanol), formaldehyde (methanol), and acetone (isopropanol); these intermediate metabolites are then further converted to acetic acid, formic acid, and/or carbon dioxide. (In people and some other primates, accumulation of formic acid after methanol ingestion results in retinal and neuronal damage; nonprimates are efficient at eliminating formic acid and therefore do not develop the blindness and cerebral necrosis seen in

primates.) Alcohols are eliminated via the urine as parent compound as well as metabolites. In dogs, up to 50% of a dose of methanol may be eliminated unchanged via the lungs.

Alcohols are GI irritants, and ingestion may result in vomiting and hypersalivation. Alcohols and their metabolites are potent CNS depressants, affecting a variety of neurotransmitters within the nervous system. Metabolites such as acetaldehyde may stimulate the release of catecholamines, which can affect myocardial function. Metabolic acidosis results from the formation of acidic intermediates, and both parent compounds and metabolites contribute to increases in osmolal gap. Hypothermia may develop due to peripheral vasodilation, CNS depression, and interference with thermoregulatory mechanisms. Hypoglycemia develops secondary to alcohol-induced depletion of pyruvate, resulting in inhibition of gluconeogenesis.

Clinical Findings and Diagnosis:

Signs generally begin within 30–60 min of ingestion and include vomiting, diarrhea, ataxia, disorientation (inebriation), depression, tremors, and dyspnea. Severe cases may progress to coma, hypothermia, seizures, bradycardia, and respiratory depression. Death is generally due to respiratory failure, hypothermia, hypoglycemia, and/or metabolic acidosis. Pneumonia secondary to aspiration of vomitus is possible.

The determination of blood alcohol levels may help to confirm the diagnosis of alcohol intoxication.

Treatment: Stabilization of severely symptomatic animals is a priority. Adequate ventilation should be maintained, and cardiovascular and acid-base abnormalities should be corrected. Seizures can be controlled with diazepam (0.5–2 mg/kg, IV) as needed. For asymptomatic animals, induction of emesis may be of benefit in the first 20–40 min after ingestion. Activated charcoal is not thought to appreciably bind small-chain alcohols and is not often recommended. Bathing with mild shampoo is recommended for significant dermal exposures. Supportive care, including thermoregulation and fluid diuresis to enhance alcohol elimination,

should be administered. Anecdotally, yohimbine (0.1 mg/kg, IV) has been used to stimulate respiration in severely comatose dogs with alcohol toxicosis.

CHLORINE BLEACHES

Exposure to undiluted chlorine bleaches may result in GI, dermal, and ocular irritation or ulceration as well as significant respiratory irritation. All species are susceptible. Because of the countercurrent anatomy and physiology of the avian lung, caged birds are at increased risk of succumbing to fumes from bleaches and other cleaning agents.

Etiology: Chlorine bleaches are primarily used as household cleaners and pool sanitizers. Household bleaches tend to contain sodium hypochlorite at 3%–10%, and pH of these products may range from 9 (mildly irritating) to >11 (corrosive). Pool treatments may contain lithium, calcium, or sodium hypochlorites at concentrations up to 70%–80%, with pH that may range from acidic to alkaline. Pets may be exposed by chewing on containers of undiluted product, drinking from buckets containing product diluted in water, or swimming in recently treated pools.

Pathogenesis: The relative hazard of a particular bleach product depends on the concentration of hypochlorite, pH, and dilution of the product. In general, levels of hypochlorite <10% tend to be mild irritants; however, if the product has a pH >11 or <3.5, alkaline or acid corrosive injury may occur. Dilution of bleaches with water per label directions will often reduce the corrosive potential of these products and make them little more than mild GI or ocular irritants. Mixing of hypochlorite and ammonia produces highly toxic chloramine gas that can cause acute respiratory distress or delayed onset of pulmonary edema within 12–24 hr of exposure.

Clinical Findings and Lesions: Ingestion of dilute or moderate pH household bleach products rarely causes more than mild vomiting, hypersalivation, depression, anorexia, and/or diarrhea. Concentrated (>10%) bleach products or products with pH >11 may cause significant GI corrosive injury. Ingestion or inhalation of significant amounts of chlorine bleach occasionally results in hypernatremia, hyperchloremia, and/or metabolic acidosis. Acute inhalation may result in

immediate coughing, gagging, sneezing, or retching. In addition to the immediate respiratory signs, animals exposed to concentrated chlorine fumes may develop pulmonary edema 12–24 hr after exposure. Ocular exposures may result in epiphora, blepharospasm, eyelid edema, and/or corneal ulceration. Dermal exposure may result in mild dermal irritation and bleaching of the hair coat. Oral, dermal, and ocular irritation or ulceration are possible. Respiratory lesions may include tracheitis, bronchitis, alveolitis, and pulmonary edema.

Treatment: For oral exposures, emesis and activated charcoal are contraindicated; instead, dilution with milk or water is recommended. Any spontaneous vomiting should be managed, and animals should be monitored for development of GI irritation/ulceration (*see below*). In cases when protracted vomiting causes electrolyte or hydration abnormalities, fluid therapy may be of benefit. For respiratory exposures, the animal should be moved to an area with fresh air and monitored for dyspnea. Stabilization of severely dyspneic animals is a must; pulmonary edema should be treated as needed. Bathing with mild shampoo and thorough rinsing is recommended for significant dermal exposures. Ocular exposures should be treated with 10–20 min of ocular irrigation with physiologic saline, followed by fluorescein staining of the cornea to detect corneal injury.

CORROSIVES

Acid or alkaline corrosives produce significant local tissue injury that can result in full-thickness burns of skin, cornea, and the mucosa of the oral cavity, esophagus, and stomach. All species are susceptible. Heavy coats may provide some protection from dermal exposure.

Etiology: Corrosives are divided into acid and alkaline corrosives. Acidic household products include anti-rust compounds, toilet bowl cleaners, gun-cleaning fluids, automotive batteries, swimming pool cleaning agents, and etching compounds. Alkaline corrosive agents include drain openers, automatic dishwasher detergents, toilet bowl cleaners, radiator cleaning agents, and swimming pool algicides and “shock” agents. In general, alkaline products with pH >11 pose risk of significant corrosive injury.

Pathogenesis: Acids produce immediate coagulative necrosis of tissue and impart significant pain on contact, which may limit exposure. Alkaline agents produce immediate, penetrating liquefactive necrosis of tissue; the lack of significant discomfort on contact with alkaline products may result in prolonged exposure. For these reasons, burns from alkaline products tend to be deeper and more extensive than burns from acidic agents. Burns from alkaline agents may take up to 12 hr after exposure to become fully apparent, whereas the extent of acid burns is usually evident shortly after contact. Esophageal burns are more common with alkaline agents, and the absence of significant oral burns does not necessarily indicate that no esophageal damage has developed. Full-thickness ulceration of the esophagus may result in pleuritis or peritonitis due to leakage of ingesta into body cavities. Esophageal burns may result in stricture formation during healing, resulting in dysphagia, megaesophagus, and aspiration pneumonia. Additionally, although the contents of the stomach may serve to buffer and dilute corrosive agents, gastric ulceration and possibly perforation may occur with significant exposures. Respiratory exposure to corrosives (especially acids) may result in respiratory distress, tracheobronchitis, or pneumonitis. Dermal or ocular exposures may result in severe ulceration of dermis or cornea.

Clinical Findings and Lesions: Clinical signs that may occur after ingestion of corrosive agents include vocalization, hypersalivation, lethargy, polydipsia, vomiting (with or without blood), abdominal pain, dysphagia, pharyngeal edema, dyspnea, and oral, esophageal, and/or gastric ulceration. In severe cases, shock may develop rapidly after exposure. Lesions are initially milky white to gray but gradually turn black as eschar formation occurs. Necrotic tissue may slough within days of exposure. Dyspnea, cyanosis, and pulmonary edema may occur secondary to inhaled corrosive agents. Dermal exposure may result in significant burns, with local pain, erythema, and tissue sloughing. Ocular exposure may cause blepharospasm, epiphora, eyelid edema, conjunctivitis, or corneal ulceration. Burns of skin, cornea, and GI mucosa range from mild ulceration to full-thickness necrosis with extensive tissue sloughing. Peritonitis or pleuritis

may develop secondary to perforating ulcers of esophagus or stomach. Respiratory lesions may include tracheitis, bronchitis, pneumonitis, pulmonary edema, or aspiration pneumonia.

Treatment: Because of the rapid action of corrosive agents, much of the damage from exposure occurs before treatment can be started. Stabilization of animals presenting as dyspneic, in shock, or with severe electrolyte abnormalities is always a priority. For recent oral exposures, immediate dilution with water or milk should be done. Under no circumstances should emesis be attempted because of the risk of further mucosal exposure to corrosive material. Likewise, gastric lavage is contraindicated because of the risk of perforation of weakened esophageal/gastric walls and the risk of further exposure of mucosa to the corrosive material as it is removed. Attempts to chemically neutralize an acid with weak alkali (or alkali with weak acid) are also contraindicated because of the production of exothermic reactions that can result in thermal burns. Activated charcoal is ineffective in cases involving ingestion of corrosives, and the presence of charcoal on damaged mucosa may impede wound healing.

After dilution, general supportive care should be instituted, including monitoring for respiratory difficulty, pain management, antibiotics (if ulcers are present), and anti-inflammatories as needed. Endoscopic evaluation of the esophagus and stomach for ulceration should be performed ~12 hr after exposure; this time frame will allow the full extent of tissue injury to become apparent. The use of corticosteroids in cases with significant esophageal mucosal injury is controversial. Corticosteroids decrease inflammation and may aid in minimizing stricture formation, but they also suppress the immune system and may enhance susceptibility to secondary infection. In animals with significant oral and/or esophageal burns, gastrostomy tubes may be necessary to provide nutrition while affected tissues heal.

Dermal or ocular exposures should be managed by flushing with copious amounts of water or physiologic saline; eyes should be flushed for a minimum of 20 min, followed by fluorescein staining. Standard topical treatments for dermal or ocular burns should be instituted as needed.

Alkaline Batteries

Ingestion of alkaline batteries poses a risk of GI tract corrosive injury and foreign body obstruction. Dogs are most commonly involved.

Etiology: Alkaline batteries are present in many household electronic products, including remote controls, hearing aids, toys, watches, computers, and calculators. Most alkaline dry cell batteries use potassium hydroxide or sodium hydroxide to generate currents. Nickel-cadmium and lithium batteries also tend to contain alkaline material.

Pathogenesis: The alkaline gel in batteries causes liquefactive necrosis of tissues on contact, resulting in burns that can penetrate deeply into tissue. Lithium disk or "button" batteries may lodge in the esophagus and generate a current against the esophageal walls, resulting in circular ulcers that have the potential to be perforating. Some battery casings may contain metals such as zinc or mercury, posing hazards of foreign body obstruction and metal toxicosis if they remain in the stomach for prolonged periods. Additionally, small batteries (especially disk batteries) may be inhaled and pose a choking hazard.

Clinical Findings and Lesions: For discussion of alkaline burns, see p 3001. Foreign body obstruction may present as vomiting, anorexia, abdominal discomfort, or tenesmus. Respiratory obstruction due to battery inhalation may present with acute onset of dyspnea and cyanosis. Mucosal burns may occur within the oral cavity, esophagus, and less commonly, stomach. Perforation of the esophagus may lead to secondary pyothorax, while gastric perforation may result in acute blood loss and/or peritonitis.

Diagnosis: Radiographs may help to confirm the diagnosis as well as the location of the battery; however, some disk batteries do not show up well on radiographs. Differential diagnoses include GI or respiratory foreign bodies and other oral, dermal, or ocular corrosive agents.

Treatment: For batteries swallowed intact without any chewing, induction of emesis may result in expulsion. Because of the risk of leakage of alkaline gel onto oral and esophageal mucosa during vomiting, emesis should not be induced if there is any possibility that the battery

casing has been punctured. When disk batteries have been ingested, 20 mL boluses of tap water every 15 min will decrease the severity and delay the development of current-induced esophageal ulceration. The decision on whether to remove a battery from the stomach depends on the size of the animal, battery size, and evidence of battery puncture. Radiography may be performed to determine the location of the battery casing; generally, batteries that have passed through the pylorus will pass through the intestinal tract uneventfully (adding bulk to the diet and judicious use of cathartics may facilitate passage). Serial radiography to verify battery location is recommended until the battery is expelled. Batteries that do not pass through the pylorus within 48 hr of ingestion are unlikely to pass on their own and may require surgical or endoscopic removal. Batteries that have obviously been punctured should be removed surgically to prevent gastric or intestinal ulceration due to leakage of alkaline gel. Endoscopic removal is not recommended in cases in which it is suspected that the battery casing has been punctured. Treatment of cases with suspected oral, esophageal, or gastric ulceration is the same as for other alkaline corrosive injuries (see p 3001). Dermal or ocular exposures to alkaline gels should be managed by copious rinsing of the area with tap water (skin) or physiologic saline solution (eyes). The affected areas should be monitored for development of ulcers, and topical therapy administered as needed.

Cationic Detergents

Exposure to cationic detergents may result in local corrosive tissue injury as well as severe systemic effects. All species are susceptible. Cats are at increased risk of oral exposure because of grooming habits.

Etiology: Cationic detergents are present in a variety of algicides, germicides (including quaternary ammonium compounds), sanitizers, fabric softeners (including dryer softener sheets), and liquid potpourris. Concentrations of cationic detergents $\leq 2\%$ have been associated with oral mucosal ulcers in cats.

Pathogenesis: Cationic detergents are locally corrosive agents, causing dermal, ocular, and mucosal injury similar to that

of alkaline corrosive agents. Additionally, exposure to cationic detergents may result in systemic effects ranging from CNS depression to pulmonary edema. The mechanism for these systemic effects is not known.

Clinical Findings and Lesions: Signs of oral exposure include oral ulceration, stomatitis, pharyngitis, hypersalivation, swollen tongue, depression, vomiting, abdominal discomfort, and increased upper respiratory noises within 6–12 hr of ingestion. Affected animals frequently have significant fever and increases in WBC counts. Systemic effects include metabolic acidosis, CNS depression, hypotension, coma, seizures, muscular weakness and fasciculation, collapse, and pulmonary edema. Dermal irritation, erythema, ulceration, and pain are possible with dermal contact. Conjunctivitis, blepharospasm, eyelid edema, lacrimation, and corneal ulceration may be seen secondary to ocular exposure. Lesions can include GI, ocular, or dermal irritation or ulceration.

Treatment: Systemic signs should be treated symptomatically, eg, diazepam (0.5–2 mg/kg, slow IV) for seizures, fluid therapy for hypotension, etc. Because of the potential for corrosive mucosal injury, induction of emesis and administration of activated charcoal are contraindicated with cationic detergents. For recent oral exposures, milk or water can be given for dilution, and the animal monitored for development of oral or esophageal burns. Oral burns should be treated the same as other corrosive injuries (*see* p 3001). Dermal and ocular exposures should be managed by thorough flushing of the affected area with tepid water or physiologic saline, followed by monitoring for development of dermal or ocular irritation or ulceration. Topical treatment for dermal or ocular burns should be instituted as needed; in severe cases, analgesics may be indicated.

DETERGENTS, SOAPS, AND SHAMPOOS

Exposures to products containing anionic and nonionic detergents generally cause mild GI irritation that responds well to symptomatic care. All animals are susceptible.

Etiology: Mild detergents, soaps, and shampoos contain anionic and nonionic

detergents; products included in this group include human and pet shampoos, liquid hand dishwashing soaps, bar bath soaps (except homemade soaps, which may contain lye), many laundry detergents, and many household all-purpose cleaners. Most are of moderate pH, but agents with pH >11 (eg, electric dishwasher detergents) are alkaline corrosives and should be treated as such (*see* p 3001).

Pathogenesis: Anionic and nonionic detergents are mild irritants; many have been pH adjusted to have minimal dermal irritation, although ocular and mucosal irritation is possible. There is no appreciable systemic absorption of these agents, and toxicity is limited to ocular, oral, or GI irritation, which is usually mild and self-limiting. Cats exposed to undiluted shampoos or other products containing sodium lauryl sulfate may develop significant respiratory compromise after inhalation during grooming, including dyspnea, increased bronchial secretions, and mild pulmonary edema. Although the exact mechanism of this syndrome is not known, it may relate to interference by the detergent with normal pulmonary surfactants.

Clinical Findings: Nausea, vomiting, and diarrhea are the most common signs. Secondary dehydration and electrolyte imbalance may develop in rare instances due to protracted vomiting or diarrhea. Mild ocular irritation is possible, with lacrimation and blepharospasm. No significant lesions beyond mild local irritation are seen. Cats grooming after application of sodium lauryl sulfate-containing products may develop moist respiratory sounds, cyanosis, and dyspnea within 1–3 hr of exposure.

Treatment: Dilution with milk or water may reduce the risk of spontaneous vomiting. Vomiting is usually self-limiting and responds to short periods of food and water restriction. In severe cases or in animals with sensitive stomachs, antiemetics may be required (eg, metoclopramide, 0.2–0.4 mg/kg, PO, SC, or IM, qid). Rarely, parenteral fluid therapy is required to correct electrolyte or hydration abnormalities due to protracted vomiting or diarrhea. For ocular exposures, irrigation of eyes using tepid water or physiologic saline for 5 min will usually suffice. For cats that have respiratory compromise, supplemental oxygen and general supportive care are recommended; in most cases, signs resolve within 24 hr.

MYCOTOXICOSES

For discussion of mycotoxicoeses in poultry, see p 2846.

Acute or chronic toxicoses can result from exposure to feed or bedding contaminated with toxins produced during growth of various saprophytic or phytopathogenic fungi or molds on cereals, hay, straw, pastures, or any other fodder. These toxins are not consistently produced by specific molds and are known as secondary (not essential) metabolites that are formed under conditions of stress to the fungus or its plant host.

A few principles characterize mycotoxic diseases: 1) The cause may not be immediately identified. 2) They are not transmissible from one animal to another. 3) Treatment with drugs or antibiotics has little effect on the course of the disease. 4) Outbreaks are often seasonal, because particular climatic sequences may favor fungal growth and toxin production. 5) Study indicates specific association with a particular feed. 6) Large numbers of fungi or their spores found on examination of feedstuffs does not necessarily indicate that toxin production has occurred. However, absence of molds does not exclude mycotoxicosis, because feed storage or preparation conditions, eg, acid treatment or high pelleting, can destroy molds while the heat-tolerant mycotoxin persists.

Diagnosis of mycotoxic disease requires a combination of information. Most veterinary mycotoxicoeses are found in large animal species, but important outbreaks can happen in pets and exotic animals. Especially important in diagnosis is the presence of a disease documented to be caused by a known mycotoxin, combined with detection of the mycotoxin in either feedstuffs or animal tissues.

Sometimes more than one mycotoxin may be present in feedstuffs, and their different toxicologic properties may cause clinical signs and lesions inconsistent with those seen when animals are dosed experimentally with pure, single mycotoxins. Some mycotoxins are immunosuppressive, which may allow viruses, bacteria, or parasites to create a secondary disease that is more obvious than the primary. When immunosuppression by a mycotoxin is

suspected, differential diagnoses must be carefully established by thorough clinical and historical evaluation, examination of production records, and appropriate diagnostic testing.

Mycotoxicoeses are generally not successfully treated with medical therapy after diagnosis. A preventive approach with recognition of risk factors and avoiding or reducing exposure is preferred. Best management practices are aimed at prevention of the occurrence of mycotoxins, inactivation of the preformed toxin in grain or feed, and adsorption or inactivation of the toxin in the GI tract. Testing of suspect grain at harvest, maintaining clean and dry storage facilities, using acid additives (eg, propionic acid) to control mold growth in storage, ensuring effective air exclusion in silage storage, and reducing storage time of prepared feeds are established procedures to prevent mycotoxin formation. Acidic additives control mold growth but do not destroy preformed toxins.

There are no specific antidotes for mycotoxins; removal of the source of the toxin (ie, the moldy feedstuff) eliminates further exposure. The absorption of some mycotoxins (eg, aflatoxin) has been effectively prevented by aluminosilicates. If financial circumstances do not allow for disposal of the moldy feed, it can be blended with unspoiled feed just before feeding to reduce the toxin concentration. This approach should be monitored by follow-up toxin analysis and may not be acceptable to regulatory agencies. Alternatively, feed with known mycotoxin concentrations can be fed to less susceptible species, remembering that some mycotoxins such as aflatoxin could result in violative food residues in the absence of illness. When contaminated feed is blended with good feed, care must be taken to prevent further mold growth by the toxigenic contaminants. This may be accomplished by thorough drying or by addition of organic acids (eg, propionic acid).

Important mycotoxic diseases occur in domestic animals worldwide (see TABLE 1).

TABLE 4 MYCOTOXICOSES IN DOMESTIC ANIMALS

Disease	Toxins (When Known)	Fungi or Molds	Regions Where Reported
Aflatoxicosis	Aflatoxins	<i>Aspergillus flavus</i> , <i>A parasiticus</i>	Widespread (warmer climatic zones)
Diplodiosis	Unknown	<i>Diplodia zeae</i>	South Africa
Ergotism	Ergot alkaloids	<i>Claviceps purpurea</i>	Widespread
	Paspalinine and paspalitremis, tremorgens	<i>C paspali</i> , <i>C cinerea</i>	Widespread
Estrogenism and vulvovaginitis	Zearalenone	<i>Fusarium graminearum</i> Perfect state: <i>Gibberella zeae</i>	Widespread
Facial eczema (Pithomycotoxico- sis)	Sporidesmins	<i>Pithomyces chartarum</i>	Widespread
Fescue foot	Ergovaline	<i>Neotyphodium coenophialatum</i>	USA, Australia, New Zealand, Italy
Fusariotoxiosis, vomiting and feed refusal in pigs	Nonmacrocyclic trichothecenes (deoxynivalenol, T-2 toxin, diacetoxyscir- penol [DAS], many other trichothecenes)	<i>Fusarium sporotrichioides</i> , <i>F culmorum</i> , <i>F graminearum</i> , <i>F nivale</i> ; other fungal species	Widespread (except for deoxynivalenol, more likely in temperate to colder climates)
Leukoencephalo- malacia	Fumonisin B ₁	<i>Fusarium verticilloides</i>	Egypt, USA, South Africa, Greece
Mycotoxic lupinosis (as distinct from alkaloid poisoning)	Phomopsins	<i>Phomopsis leptostromiformis</i>	Widespread

TABLE 4 MYCOTOXICOSES IN DOMESTIC ANIMALS (continued)

Contaminated Toxic Foodstuff	Animals Affected	Signs and Lesions
Moldy peanuts, soybeans, cottonseeds, rice, sorghum, corn (maize), other cereals	All poultry, pigs, cattle, sheep, dogs	Major effects in all species are slow growth and hepatotoxicosis. <i>See also</i> AFLATOXICOSIS, p 3011, and MYCOTOXICOSES IN POULTRY, p 2846.
Moldy corn (maize)	Cattle, sheep	Nervous system disorders, cold and insensitive limbs. Recovery usual on removal of source.
Seed heads of many grasses, grains	Cattle, horses, pigs, poultry	Peripheral gangrene, late gestation suppression of lactation initiation. <i>See</i> p 3012.
Seed heads of paspalum grasses	Cattle, horses, sheep	Acute tremors and ataxia. <i>See</i> PASPALUM STAGGERS, p 3019.
Moldy corn (maize) and pelleted cereal feeds, standing corn, corn silage, other grains	Pigs, cattle, sheep, poultry	Vulvovaginitis in pigs, anestrus or pseudopregnancy in mature sows, early embryonic death of swine embryos, estrogenism in cattle and sheep, reduced egg production in poultry. <i>See also</i> p 3014.
Toxic spores on pasture litter	Sheep, cattle, farmed deer	<i>See also</i> p 3015.
Tall fescue grass (<i>Lolium arundinacea</i>)	Cattle, horses	Lameness, weight loss, hyperthermia, heat intolerance, dry gangrene of extremities, agalactia, thickened fetal membranes. <i>See also</i> p 3016.
Cereal crops, moldy roughage	Pigs, cattle, horses, poultry	Vomiting and feed refusal (deoxynivalenol), loss of appetite and milk production, diarrhea, staggers, skin irritation, immunosuppression; recovery (from T-2, DAS) on removal of contaminated feed. <i>See also</i> p 3020.
Moldy corn (maize)	Horses, other Equidae, pigs	Depends on degree and specific site of brain lesion. <i>See also</i> p 3017.
Moldy seed, pods, stubble, and haulm of several <i>Lupinus</i> spp affected by <i>Phomopsis</i> stem blight	Sheep, occasionally cattle, horses, pigs	Lassitude, inappetence, stupor, icterus, marked liver injury. Usually fatal. <i>See also</i> p 3018.

(continued)

TABLE 4 MYCOTOXICOSES IN DOMESTIC ANIMALS (continued)

Disease	Toxins (When Known)	Fungi or Molds	Regions Where Reported
Myrotheciotoxico- sis, dendrochio- toxicosis	Macrocylic trichothecenes (verrucarins, roridins, etc)	<i>Myrothecium verrucaria</i> , <i>M roridum</i>	Southeast Europe, former USSR
	Macrocylic trichothecenes (baccharinoids)	<i>M verrucaria</i>	Brazil
Ochratoxicosis	Ochratoxin, also citrinin	<i>Aspergillus ochraceus</i> and others, <i>Penicillium viridicatum</i> , <i>P citrinum</i>	Widespread
<i>Penicillium</i> -associ- ated tremorgens	Penitrem A	<i>P crustosum</i> , <i>P cyclopium</i> , <i>P commune</i>	Widespread
	Roquefortine	<i>P roqueforti</i>	
Perennial ryegrass staggers	Lolitrems	<i>Lolium perenne</i> , <i>Neotyphodium lolii</i> , an endophyte fungus confined to <i>L perenne</i>	Australia, New Zealand, Europe, USA
Poultry hemor- rhagic syndrome	Probably aflatoxins and rubratoxins	Probably <i>Aspergil- lus flavus</i> , <i>A clavatus</i> , <i>Penicil- lium purpuroge- num</i> , <i>Alternaria</i> sp	USA
Pulmonary edema, emphysema	4-Ipomeanol	<i>Fusarium solani</i>	USA
Porcine pulmonary edema	Fumonisin B ₁ and Fumonisin B ₂	<i>Fusarium verticilloides</i>	USA, South Africa
Slobbers syndrome	Slaframine (and swainsonine)	<i>Rhizoctonia leguminicola</i>	USA

TABLE 4 MYCOTOXICOSES IN DOMESTIC ANIMALS (*continued*)

Contaminated Toxic Foodstuff	Animals Affected	Signs and Lesions
Moldy rye stubble, straw	Sheep, cattle, horses	Acute—diarrhea, respiratory distress, hemorrhagic gastroenteritis, immunosuppression, death. Chronic—ulceration of GI tract, unthriftiness, gradual recovery. <i>See also</i> p 3020.
Plants of <i>Baccharis</i> spp that contain the toxins	Cattle, other herbivores	Epithelial necrosis of GI tract. <i>See also</i> p 3020.
Moldy barley, corn (maize), wheat	Pigs, poultry	Perirenal edema, enlarged pale kidneys with cortical cysts, and tubular degeneration and fibrosis; immunosuppression, polyuria and polydipsia.
Cereal grains, cheese, fruit, meats, nuts, refrigerated foods; compost	Cattle, dogs, horses, sheep	Neurotoxic signs, including continual tremors, seizures, hyperexcitability, ataxia. Vomiting and CNS signs in dogs.
As above, and in silage		
Endophyte-infected ryegrass pastures	Sheep, cattle, horses, deer	Tremors, incoordination, collapse, convulsive spasms. <i>See also</i> RYEGRASS STAGGERS, p 3153.
Moldy grain and meal	Growing chickens	Depression, anorexia, no weight gain, widespread internal hemorrhages, sometimes aplastic anemia, death. <i>See</i> MYCOTOXICOSES IN POULTRY, p 2846.
Moldy sweet potatoes	Cattle	Acute pulmonary edema, leading to interstitial pneumonia and emphysema.
Corn	Swine	Acute interlobular pulmonary edema and hydrothorax cause anoxia and cyanosis. Survivors may develop icterus and chronic hepatotoxicosis.
Black patch disease, legumes (notably red clover) eaten as forage or hay	Sheep, cattle	Salivation, bloat, diarrhea, sometimes death. Recovery usual when removed from clover. <i>See also</i> SLAFRAMINE TOXICOSIS, p 3019.

(*continued*)

TABLE 4 MYCOTOXICOSES IN DOMESTIC ANIMALS (continued)

Disease	Toxins (When Known)	Fungi or Molds	Regions Where Reported
Stachybotryotoxigenesis	Macrocyclic trichothecenes (satratoxin, roridin, verrucarol)	<i>Stachybotrys atra</i> (<i>S alternans</i>)	Former USSR, southeast Europe
Sweet clover poisoning	Dicumarol	<i>Penicillium</i> spp, <i>Mucor</i> spp, <i>Aspergillus</i> spp	North America
Tremorgen ataxia syndrome	Penitrem, verruculogen, paxilline, fumitremogins, aflatoxins, roquefortine	<i>Penicillium crustosum</i> , <i>P puberulum</i> , <i>P verruculosum</i> , <i>P roqueforti</i> , <i>Aspergillus flavus</i> , <i>A fumigatus</i> , <i>A clavatus</i> , and others	USA, South Africa, probably worldwide

Managing a Suspected Mycotoxicosis

When mycotoxicosis is suspected, corrective actions could include the following:

- 1) Change the feed even when a specific mycotoxin is not identified.
- 2) Thoroughly inspect storage bins, mixing equipment, and feeders for caking, molding, or musty odors.
- 3) Remove contaminated feed and clean equipment and sanitize with hypochlorite (laundry bleach) to reduce contaminating fungi.
- 4) Analyze for known mycotoxins.
- 5) Use spore counts or fungal cultures for some indication of potential mycotoxin production.
- 6) If storage conditions or grain moisture are adverse, use a mold inhibitor to reduce or delay mold growth. Remember, mold inhibitors do not destroy preformed toxins.
- 7) Use a mycotoxin adsorbent if appropriate for the mycotoxin suspected.
- 8) Save a representative sample of each diet mixed until animals are at 1 mo beyond when the feed was consumed.
- 9) Take a representative sample of suspect feed after milling by passing a cup through a moving auger stream at frequent intervals, mixing samples thoroughly, and saving a 4.5-kg (10-lb) sample for analysis. Alternatively, use probe sampling of recently blended grain in bins or trucks at five locations in each structure for each 6 feet of depth. Freeze or dry samples, and submit for analysis in a paper bag (not

plastic). Dry samples are preferable in a paper bag to prevent condensation during transport and storage. Samples should be dried at 176°–194°F (80°–90°C) for ~3 hr to reduce moisture to 12%–13%. If mold studies are to be done, dry at 140°F (60°C) for 6–12 hr to preserve fungal activity.

Mycotoxin Adsorbents

Adsorption of mycotoxins in contaminated feeds is an area of active research. Aflatoxins are effectively adsorbed by the aluminosilicate feed additives (see below). However, this group of adsorbents are of little or limited use for other mycotoxins. Trichothecene mycotoxins, including deoxynivalenol, are not readily adsorbed by common feed additives. The aluminosilicate adsorbents that are effective against aflatoxins have limited or no benefits against trichothecenes. Sodium bentonite is an effective adsorbent for aflatoxins in cattle and poultry but appears ineffective for trichothecenes and zearalenone. The polymeric glucosylated adsorbents (GM) are useful for poultry growth and feed consumption with low natural concentrations of aflatoxin, ochratoxin, T-2 toxin, and zearalenone. When added to *Fusarium*-contaminated diets, GM reduced the number of stillborn piglets compared with controls. GM adsorbent efficacy for ruminants has been

TABLE 4 MYCOTOXICOSES IN DOMESTIC ANIMALS (continued)

Contaminated Toxic Foodstuff	Animals Affected	Signs and Lesions
Moldy roughage, other contaminated feed	Horses, cattle, sheep, pigs	Stomatitis and ulceration, anorexia, leukopenia, extensive hemorrhages in many organs, inflammation and necrosis in the gut, immunosuppression. <i>See also</i> TRICHOThECENE TOXICOSIS, p 3020.
Sweet clover (<i>Melilotus</i> spp)	Cattle, horses, sheep	Vitamin K antagonism with coagulopathy and hemorrhage. <i>See also</i> p 3156.
Moldy feed; high-protein food products, even under refrigeration, eg, cream cheese, walnuts	All species, but dogs are quite susceptible	Tremors, polypnea, ataxia, collapse, convulsive spasms.

variable in different studies. Cholestyramine has been an effective binder of fumonisins and zearalenone *in vitro* and for fumonisins in animal experiments, but response in cattle is unknown. Although various adsorbents are allowed for animal feed in various countries, none is FDA approved in the USA.

AFLATOXICOSIS

Aflatoxins are produced by toxigenic strains of *Aspergillus flavus* and *A. parasiticus* on peanuts, soybeans, corn (maize), and other cereals either in the field or during storage when moisture content and temperatures are sufficiently high for mold growth. Usually, this means consistent day and night temperatures >70°F. The toxic response and disease in mammals and poultry varies in relation to species, sex, age, nutritional status, and the duration of intake and level of aflatoxins in the ration. Earlier recognized disease outbreaks called "moldy corn toxicosis," "poultry hemorrhagic syndrome," and "*Aspergillus* toxicosis" may have been caused by aflatoxins.

Aflatoxicosis occurs in many parts of the world and affects growing poultry (especially ducklings and turkey poults), young pigs, pregnant sows, calves, and dogs. Adult cattle, sheep, and goats are relatively resistant to the acute form of the disease but

are susceptible if toxic diets are fed over long periods. Experimentally, all species of animals tested have shown some degree of susceptibility. Dietary levels of aflatoxin (in ppb) generally tolerated are ≤50 in young poultry, ≤100 in adult poultry, ≤50 in weaner pigs, ≤200 in finishing pigs, <50 in dogs, <100 in calves, and <300 in cattle. Approximately two times the tolerable levels stated is likely to cause clinical disease, including some mortality. Dietary levels as low as 10–20 ppb result in measurable metabolites of aflatoxin (aflatoxin M₁ and M₂) being excreted in milk; feedstuffs that contain aflatoxins should not be fed to dairy cows. Acceptable regulatory values in milk may range from 0.05 ppb to 0.5 ppb in different countries; individual state or federal regulatory agencies should be consulted when contamination occurs.

Aflatoxins are metabolized in the liver to an epoxide that binds to macromolecules, especially nucleic acids and nucleoproteins. Their toxic effects include mutagenesis due to alkylation of nuclear DNA, carcinogenesis, teratogenesis, reduced protein synthesis, and immunosuppression. Reduced protein synthesis results in reduced production of essential metabolic enzymes and structural proteins for growth. The liver is the principal organ affected. High dosages of aflatoxins result in hepatocellular necrosis; prolonged low dosages result in

reduced growth rate, immunosuppression, and liver enlargement.

Clinical Findings: In acute outbreaks, deaths occur after a short period of inappetence; other acute signs include vomiting, depression, hemorrhage, and icterus. Subacute outbreaks are more usual, with unthriftiness, weakness, anorexia, reduced growth and feed efficiency, and occasional sudden deaths. Laboratory changes in most species are related to liver damage, coagulopathy, and impaired protein synthesis. Specific laboratory changes include increased AST, ALT, and alkaline phosphatase; hypothermia, prolonged prothrombin and activated partial thromboplastin times, hyperbilirubinemia, hypocholesterolemia, hypoalbuminemia, and variable thrombocytopenia. Generally, aflatoxin concentrations in feed twice the tolerable levels given above are associated with acute aflatoxicosis. Recently, acute and fatal aflatoxicosis with many of these signs and laboratory changes has been documented in dogs. Frequently, there is a high incidence of concurrent infectious disease, often respiratory, that responds poorly to the usual drug therapy. Dairy cattle experience inappetence, and ruminants may have decreased ruminal contractions at high concentrations (>1,000 ppb) of aflatoxins. Liver damage can lead to reduced clotting factor synthesis with acute to chronic hemorrhage. Subclinical effects are reduced growth rate and feed efficiency, hypoproteinemia, and reduced resistance to some infectious diseases despite vaccination.

Lesions: In acute cases, there are widespread hemorrhages and icterus. The liver is the major target organ. Microscopically, the liver is enlarged and shows marked fatty accumulations and massive centrilobular necrosis and hemorrhage. In subacute cases, the hepatic changes are not so pronounced, but the liver is somewhat enlarged and firmer than usual. There may be edema of the gallbladder. Microscopically, the liver shows periportal inflammatory response and proliferation and fibrosis of the bile ductules; the hepatocytes and their nuclei (megalocytosis) are enlarged. The GI mucosa may show glandular atrophy and associated inflammation. Rarely, there may be tubular degeneration and regeneration in the kidneys. Prolonged feeding of low concentrations of aflatoxins may result in diffuse liver fibrosis (cirrhosis) and, rarely, carcinoma of the bile ducts or liver.

Diagnosis: Disease history, laboratory data, necropsy findings, and microscopic

examination of the liver should indicate the nature of the hepatotoxin, but hepatic changes are somewhat similar in *Senecio* poisoning (see p 3150). The presence and levels of aflatoxins in the feed should be determined. Acutely affected animals have increases in liver enzymes (alkaline phosphatase, AST, or ALT), bilirubin, serum bile acids, and prothrombin time. Chronic exposure can cause hypoproteinemia (including decrease in both albumin and globulin). Aflatoxin M₁ (principal metabolite of aflatoxin B₁) can be detected in urine, liver, kidney, or milk of lactating animals if toxin intakes are high. Aflatoxin residues in organs and dairy products generally are eliminated within 1–3 wk after exposure ends.

Control: Contaminated feeds can be avoided by monitoring batches for aflatoxin content. Local crop conditions (drought, insect infestation) should be monitored as predictors of aflatoxin formation. Young, newly weaned, pregnant, and lactating animals require special protection from suspected toxic feeds. Dilution with noncontaminated feedstuffs is one possibility, but this may not be acceptable on a regulatory basis. Cleaning to remove lightweight or broken grains will often substantially reduce mycotoxin concentration in remaining grain. Ammoniation reduces aflatoxin contamination in grain but is not currently approved by the FDA for use in food animals in the USA because of uncertainty about by-products produced.

Numerous products are marketed as anticaking agents to sequester or “bind” aflatoxins and reduce absorption from the GI tract. One effective binder for aflatoxins is hydrated sodium calcium aluminosilicates (HSCAS), which reduce the effects of aflatoxin when fed to pigs or poultry at 10 lb/ton (5 kg/tonne). They also provide substantial protection against dietary aflatoxin. HSCAS reduce aflatoxin M₁ in milk by ~50% but do not eliminate residues of aflatoxin M₁ in milk from dairy cows fed aflatoxin B₁. Other adsorbents (sodium bentonites, polymeric glucomannans) have shown variable but partial efficacy in reducing low-level aflatoxin residues in poultry and dairy cattle. To date, the FDA has not licensed any product for use as a “mycotoxin binder” in animal feeds.

ERGOTISM

Ergotism is a worldwide disease of farm animals that results from ingestion of sclerotia of the parasitic fungus *Claviceps*

purpurea, which replaces the grain or seed of rye and other small grains or forage plants, such as the bromes, bluegrasses, fescues, and ryegrasses. The hard, black, elongated sclerotia may contain varying quantities of ergot alkaloids, of which ergotamine and ergonovine (ergometrine) are pharmacologically most important. Cattle, pigs, sheep, and poultry are involved in sporadic outbreaks, and most other species are susceptible. Poisoning can come from grazing seed heads or from infected grains in concentrate rations.

Etiology: Ergot causes vasoconstriction by direct action on the muscles of the arterioles, and repeated doses injure the vascular endothelium. These actions initially reduce blood flow and eventually lead to complete stasis with terminal necrosis of the extremities due to thrombosis. A cold environment predisposes the extremities to gangrene. In addition, ergot also causes stimulation of the CNS, followed by depression. Ergot alkaloids inhibit pituitary release of prolactin in many mammalian species, with failure of both mammary development in late gestation and delayed initiation of milk secretion, resulting in agalactia at parturition. Ergot alkaloids have also been associated with heat intolerance, dyspnea, and reduced milk production in dairy cattle, similar to the "summer syndrome" described for fescue toxicosis.

Clinical Findings and Lesions: Cattle may be affected by eating ergotized hay or grain or occasionally by grazing seeded pastures infested with ergot. Lameness, the first sign, may appear 2–6 wk or more after initial ingestion, depending on the concentration of alkaloids in the ergot and the quantity of ergot in the feed. Hindlimbs are affected before forelimbs, but the extent of involvement of a limb and the number of limbs affected depends on the daily intake of ergot. Body temperature and pulse and respiration rates are increased. **Epidemic hyperthermia** and hypersalivation may also occur in cattle poisoned with *C purpurea* (see **▲ ISO FESCUE POISONING**, p 3016). Ergot alkaloids may interfere with embryonic development in pregnant females.

Associated with the lameness are swelling and tenderness of the fetlock joint and pastern. Within ~1 wk, sensation is lost in the affected part, an indented line appears at the limit of normal tissue, and dry gangrene affects the distal part. Eventually, one or both claws or any part of the limbs up to the hock or knee may be

sloughed. In a similar way, the tip of the tail or ears may become necrotic and slough. Exposed skin areas, such as teats and udder, appear unusually pale or anemic. Abortion is not seen.

The most consistent lesions at necropsy are in the skin and subcutaneous parts of the extremities. The skin is normal to the indented line, but beyond, it is cyanotic and hardened in advanced cases. Subcutaneous hemorrhage and some edema occur proximal to the necrotic area.

In pigs, ingestion of ergot-infested grains may result in reduced feed intake and reduced weight gain. Occasionally, swine may show necrosis of the tips of ears or tail. If fed to pregnant sows, ergotized grains result in lack of udder development with agalactia at parturition, and the piglets born may be smaller than normal. Most of the litter die within a few days because of starvation. No other clinical signs or lesions are seen.

Clinical signs in sheep are similar to those in cattle. Additionally, the mouth may be ulcerated, and marked intestinal inflammation may be seen at necropsy. A convulsive syndrome has been associated with ergotism in sheep.

Diagnosis: Diagnosis is based on finding the causative fungus (ergot sclerotia) in grains, hay, or pastures provided to livestock showing signs of ergotism. Ergot alkaloids may be extracted and detected in suspect ground grain meals. At 200–600 ppb, ergot alkaloids may cause clinical signs and effects; however, this is influenced by the relative amounts of various ergot alkaloids in the grain.

Identical signs and lesions of lameness, and sloughing of the hooves and tips of ears and tail, are seen in fescue foot in cattle grazing in winter on tall fescue grass infected with an endophyte fungus, in which the ergot alkaloid ergovaline is considered a major toxic principle. In gilts and sows, lactation failure not associated with ergot alkaloids must be differentiated from prolactin inhibition due to ergot.

Treatment: In horses, parenteral use of the dopamine D2 antagonist domperidone (1.1 mg/kg, PO, bid for 10–14 days) is effective in prevention of agalactia from ergot alkaloids in fescue. Use against the same alkaloids produced by *C purpurea* could be medically logical (see p 3016).

Control: Intake of ergot bodies should be <0.1% of the total diet, and concentrations of ergot alkaloids should be <100 ppm in the

total diet. Ergotism can be controlled by an immediate change to an ergot-free diet. In pregnant sows, however, removal of ergot in late gestation (<1 wk before parturition) may not correct the agalactia syndrome, and animals with clinical peripheral gangrene will not likely recover. Under pasture feeding conditions, frequent grazing or topping of pastures prone to ergot infestation during the summer months reduces flower-head production and helps control the disease. Grain that contains even small amounts of ergot should not be fed to pregnant or lactating sows.

ESTROGENISM AND VULVOVAGINITIS

(*Fusarium* estrogenism)

Fusarium spp molds are extremely common and often contaminate growing plants and stored feeds. Corn (maize), wheat, and barley are commonly contaminated. In moderate climates under humid weather conditions, *F. graminearum* may produce zearalenone, one of the resorcyclic acid lactones (RALs). Zearalenone (formerly called F₂ toxin) is a potent nonsteroidal estrogen and is the only known mycotoxin with primarily estrogenic effects. Often, zearalenone is produced concurrently with deoxynivalenol. Depending on the ratio of these two mycotoxins, signs of reduced feed intake or reproductive dysfunction may predominate, but presence of deoxynivalenol may limit exposure to zearalenone, thus reducing its practical effect.

Zearalenone binds to receptors for 17 β -estradiol, and this complex binds to estradiol sites on DNA. Specific RNA synthesis leads to signs of estrogenism. Zearalenone is a weak estrogen with potency 2–4 times less than estradiol. Under controlled administration, zearalanol, a closely related RAL, is widely used in cattle as an anabolic agent.

Estrogenism due to zearalenone was first clinically recognized as vulvovaginitis in prepubertal gilts fed moldy corn (maize), but zearalenone is occasionally reported as a suspected disease-causing agent for sporadic outbreaks in dairy cattle, sheep, chickens, and turkeys. High dietary concentrations (>20–30 ppm) are required to produce infertility in cattle and sheep, and extremely high dosages are required to affect poultry.

Etiology: Zearalenone has been detected in corn, oats, barley, wheat, and sorghum (both fresh and stored); in rations

compounded for cattle and pigs; in corn ensiled at the green stage; and very rarely in hay. It has been detected occasionally in samples from pastures in temperate climates at levels believed sufficient to cause reproductive failure of grazing herbivores.

Clinical Findings: Clinical effects cannot be distinguished from excessive estrogen administration. Physical and behavioral signs of estrus are induced in young gilts by as little as 1 ppm dietary zearalenone. In pigs, zearalenone primarily affects weaned and prepubertal gilts, causing hyperemia and enlargement of the vulva (known as vulvovaginitis). There is hypertrophy of the mammary glands and uterus, and abdominal straining results in prolapse of the uterus in severe cases. Removal of affected grain results in return to normal in ~1 wk.

Zearalenone causes reproductive toxicosis in sexually mature sows by inhibiting secretion and release of follicle-stimulating hormone (FSH), resulting in arrest of preovulatory ovarian follicle maturation. Reproductive effects in sexually mature sows depend on time of consumption. Zearalenone fed at 3–10 ppm on days 12–14 of the estrous cycle in open gilts results in retention of corpora lutea and prolonged anestrus (pseudopregnancy) for up to 40–60 days. Zearalenone fed at ≥ 30 ppm in early gestation (7–10 days after breeding) may prevent implantation and cause early embryonic death. Zearalenone metabolites can be excreted in milk of exposed sows, resulting in hyperestrogenic effects in their nursing piglets.

In cattle, dietary concentrations >10 ppm may cause reproductive dysfunction in dairy heifers, although mature cows may tolerate up to 20 ppm.

Young males, both swine and cattle, may become infertile, with atrophy of the testes. However, mature boars appear unaffected by as much as 200 ppm dietary zearalenone.

Ewes may show reduced reproductive performance (reduced ovulation rates and numbers of fertilized ova, and markedly increased duration of estrus) and abortion or premature live births.

Lesions: Lesions in pigs include ovarian atrophy and follicular atresia, uterine edema, cellular hypertrophy in all layers of the uterus, and a cystic appearance in degenerative endometrial glands. The mammary glands show ductal hyperplasia and epithelial proliferation. Squamous metaplasia is seen in the cervix and vagina. Sexually mature sows will have retained

corpora lutea for 40–70 days after exposure, consistent with signs of pseudopregnancy.

Diagnosis: Diagnosis is based on reproductive performance in the herd or flock, clinical signs, history of diet-related occurrence, and excluding other known causes of infertility. Chemical analysis of suspect feed for zearalenone and careful examination of reproductive organs at necropsy are required. As a bioassay, virgin prepubertal mice fed diets or extracts of zearalenone-contaminated feed demonstrate enlarged uteri and vaginal cornification typical of estrogens.

Differential diagnoses include reproductive tract infections and other causes of impaired fertility such as diethylstilbestrol in the diet of housed stock. In grazing herbivores, especially sheep, the plant estrogens (eg, isoflavones associated with some varieties of subterranean and red clovers, and coumestans in certain fodders [eg, alfalfa]) should be considered.

Control: Unless stock are severely or chronically affected, usually reproductive functions recover and signs regress 1–4 wk after intake of zearalenone stops. However, multiparous sows may remain anestrus up to 8–10 wk.

Management of swine with hyperestrogenism should include changing the grain immediately. Signs should stop within 1 wk. Animals should be treated symptomatically for vaginal or rectal prolapse and physical damage to external genitalia. For sexually mature sows with anestrus, one 10-mg dose of prostaglandin $F_2\alpha$, or two 5-mg doses on successive days, has corrected anestrus caused by retained corpora. Alfalfa and alfalfa meal fed to swine at 25% of the ration may reduce absorption and increase fecal excretion of zearalenone, but this is often not considered practical. Feeding activated charcoal, cholestyramine, or alfalfa meal may reduce zearalenone absorption and retention, but the high concentrations needed generally render this impractical.

FACIAL ECZEMA

(Pithomycotoxicosis)

In this mycotoxic disease of grazing live-stock, the toxic liver injury commonly results in photodynamic dermatitis. In sheep, the face is the only site of the body readily exposed to ultraviolet light, hence the common name. The disease is most common in New Zealand but also occurs in Australia, France, South Africa, several

South American countries, and probably North America. Sheep, cattle, and farmed deer of all ages can contract the disease, but it is most severe in young animals.

Etiology and Pathogenesis:

Sporidesmins are secondary metabolites of the saprophytic fungus *Pithomyces chartarum*, which grows on dead pasture litter. The warm ground temperatures and high humidity required for rapid growth of this fungus restrict disease occurrence to hot summer and autumn periods shortly after warm rains. By observing weather conditions and estimating toxic spore numbers on pastures, danger periods can be predicted and farmers alerted.

The sporidesmins are excreted via the biliary system, in which they produce severe cholangitis and pericholangitis as a result of tissue necrosis. Biliary obstruction may be seen, which restricts excretion of bile pigments and results in jaundice. Similarly, failure to excrete phylloerythrin in bile leads to photosensitization.

Previous ingestion of toxic spores causes potentiation; thus, a succession of small intakes of the spores can lead to subsequent severe outbreaks.

Clinical Findings, Lesions, and

Diagnosis: Few signs are apparent until photosensitization and jaundice appear ~10–14 days after intake of the toxins. Animals frantically seek shade. Even short exposure to the sun rapidly produces the typical erythema and edema of photodermatitis in nonpigmented skin. The animals suffer considerably, and deaths occur from one to several weeks after photodermatitis appears.

Characteristic liver and bile duct lesions are seen in all affected animals whether photosensitized or not. In acute cases showing photodermatitis, livers are initially enlarged, icteric, and have a marked lobular pattern. Later, there is atrophy and marked fibrosis. The shape is distorted, and large nodules of regenerated tissue appear on the surface. In subclinical cases, livers often develop extensive areas in which the tissue is depressed and shrunken below the normal contour, which distorts and roughens the capsule. Generally, these areas are associated with fibrosis and thickening of corresponding bile ducts. The bladder mucosa commonly shows hemorrhagic or bile pigment-stained ulcerative erosions with circumscribed edema.

The clinical signs together with characteristic liver lesions are pathognomonic. In live animals, high levels of hepatic enzymes may reflect the extensive injury to the liver.

Control: To minimize intake of pasture litter and toxic spores, short grazing should be avoided. Other feedstuffs should be fed during danger periods; encouraging clover dominance in pastures helps to provide a milieu unsuited to growth and sporulation of *P. chartarum* on litter.

The application of benzimidazole fungicides to pastures considerably restricts the buildup of *P. chartarum* spores and reduces pasture toxicity. A pasture area calculated at 1 acre (0.45 hectare)/15 cows or 100 sheep should be sprayed in midsummer with a suspension of thiabendazole. When danger periods of fungal activity are predicted, animals should be allowed only on the sprayed areas. The fungicide is effective within 4 days after spraying, provided that no more than 1 in. (2.5 cm) of rain falls within 24 hr during the 4-day period. After this time, heavy rainfall does little to reduce the effectiveness of spraying, because the thiabendazole becomes incorporated within the plants. Pastures will then remain safe for ~6 wk, after which spraying should be repeated to ensure protection over the entire dangerous season.

Sheep and cattle can be protected from the effects of sporidesmin if given adequate amounts of zinc. Zinc may be administered by drenching with zinc oxide slurry, by spraying pastures with zinc oxide, or by adding zinc sulfate to drinking water.

Sheep may be selectively bred for natural resistance to the toxic effects of sporidesmin. The heritable trait for resistance is high. Ram sires are now being selected in stud and commercial flocks for resistance either by natural field challenge or by low-level, controlled dosage of ram lambs with sporidesmin.

FESCUE POISONING

Fescue Lameness

(Fescue foot)

Fescue lameness, which resembles ergot poisoning, is believed to be caused by ergot alkaloids, especially ergovaline, produced by the endophyte fungus *Neotyphodium coenophialum* in tall fescue grass (*Lolium arundinaceum*, formerly *Festuca arundinacea*). It begins with lameness in one or both hindfeet and may progress to necrosis of the distal part of the affected limb(s). The tail and ears also may be affected independently of the lameness. In addition to gangrene of these extremities, animals may show loss of body mass, an arched back, and a rough coat. Outbreaks

have been confirmed in cattle, and similar lesions have been reported in sheep.

Tall fescue is a cool-season perennial grass adapted to a wide range of soil and climatic conditions; it is used in Australia and New Zealand for stabilizing the banks of watercourses. It is the predominant pasture grass in the transition zone in the eastern and central USA. Fescue lameness has been reported in Kentucky, Tennessee, Florida, California, Colorado, and Missouri, as well as in New Zealand, Australia, and Italy.

The causative toxic substance, ergovaline, has actions similar to those produced by sclerotia of *Claviceps purpurea*. However, ergot poisoning (see p 3012) is not the cause of fescue lameness. Ergotism is most prevalent in late summer when the seed heads of grass mature. Fescue lameness is most common in late fall and winter and has been reproduced in cattle by feeding dried fescue free of seed heads and ergot. However, occasionally, ergotized fescue seed produced in early summer may inadvertently be baled and result in ergot toxicosis instead of or in addition to fescue toxicosis.

The endophyte fungus *N. coenophialum* growing within the fescue plant can synthesize ergot alkaloids. The ergot alkaloid ergovaline has been detected in toxic fescue and constitutes ~90% of the ergopeptide alkaloids produced. Ergovaline content of infected tall fescue often ranges from 100 to 500 ppb, and >200 ppb is considered a toxic concentration. Susceptible species from most to least sensitive are horses, cattle, and sheep. Endophyte-infected fescue that does not produce ergovaline has not caused fescue toxicosis. In cattle, >90% of ergovaline metabolites are found in urine. Removal of animals from infected fescue pasture reduces urinary ergovaline below detectable concentrations within 48 hr.

Ergovaline is an agonist for dopamine D2 receptors, which initiate several physiologic abnormalities. First, inhibition of prolactin secretion causes agalactia in horses and swine and reduced lactation in cattle. The dopaminergic effect also causes imbalances of progesterone and estrogen, associated with early parturition for cattle and prolonged gestation with oversized fetuses in mares. Finally, inadequate prolactin disturbs the hypothalamic thermoregulatory center, leading to temperature intolerance when environmental temperature exceeds 31°C (88°F).

Some reports indicate an increased incidence of fescue lameness as plants age and after severe droughts. Strains of tall

fescue vary in their toxicity (eg, Kentucky-31 is more toxic than Fawn) because of variation in infection level with the fungus and to high variability within a strain. In some Kentucky-31 fescues, infection levels cannot be detected. High nitrogen applications appear to enhance toxicity. Susceptibility of cattle is subject to individual variation.

Low environmental temperature may exacerbate the lesions of fescue lameness; however, high temperatures increase the severity of a toxic problem known as **epidemic hyperthermia** or "summer syndrome," in which a high proportion of a herd of cattle exhibits hypersalivation and hyperthermia. The toxin appears to be a vasoconstrictor acting as an α_2 -adrenergic agonist on blood vessels; this promotes hyperthermia in hot weather and results in cold extremities during cold weather. Another cause of this is poisoning with *C. purpurea* (ergot alkaloids).

Erythema and swelling of the coronary region occur, and cattle are alert but lose weight and may be seen "paddling" or weight-shifting. The back is slightly arched, and knuckling of a hind pastern may be an initial sign. There is progressive lameness, anorexia, depression, and later, dry gangrene of the distal limbs (hindlimbs first). Signs usually develop within 10–21 days after turnout into a fescue-contaminated pasture in fall. A period of frost tends to increase the incidence.

For control, all infected forage should be removed.

Summer Fescue Toxicosis

Summer fescue toxicosis is a warm season condition characterized by reduced feed intake and weight gains or milk production. The toxin(s) affects cattle, sheep, and horses during the summer when they are grazing or being fed tall fescue forage or seed contaminated with the endophytic fungus *Neotyphodium coenophialum*. The severity of the condition varies from field to field and year to year.

Signs other than reduced performance, which may appear within 1–2 wk after fescue feeding is started, include fever, tachypnea, rough coat, lower serum prolactin levels, and excessive salivation. The animals seek wet spots or shade. Lowered reproductive performance also has been reported. Agalactia has been reported for both horses and cattle. Thickened placentas, delayed parturition, and birth of weak foals have been reported in horses. The severity increases when

environmental temperatures are $>75^{\circ}$ – 80° F (24° – 27° C) and if high nitrogen fertilizer has been applied to the grass.

Medical treatment for equine agalactia/reproductive syndrome is domperidone administered at 1.1 mg/kg, PO, bid for 10–14 days. For control and prevention, toxic tall fescue pastures must either be destroyed and reseeded with seed that does not contain endophytic fungus, or infected fields must be managed to avoid the high risk factor. Transfer of the fungus from plant to plant is primarily, if not solely, through infected seed. Not using pastures during hot weather, diluting tall fescue pastures with interseeded legumes, clipping or close grazing of pastures to reduce seed formation, or offering other feedstuffs help reduce severity. Removing pregnant horses or cattle 1 mo before parturition will usually prevent parturition- and lactation-related problems. Specific feed additives may provide some protection against contaminated hay. Yeast cell derivatives known as glucomannans are reported to improve performance by preventing toxin absorption in cattle; a seaweed product is reported to lessen the immunosuppressive effects of toxic tall fescue. (See also ABDOMINAL FAT NECROSIS, p 360.)

FUMONISIN TOXICOSIS

Fumonisin is responsible for two well-described diseases of livestock, equine leukoencephalomalacia and porcine pulmonary edema.

Equine leukoencephalomalacia is a mycotoxic disease of the CNS that affects horses, mules, and donkeys. It occurs sporadically in North and South America, South Africa, Europe, and China. It is associated with the feeding of moldy corn (maize), usually over a period of several weeks. Fumonisin is produced worldwide primarily by *Fusarium verticillioides* (previously *F. moniliforme* Sheldon) and *F. proliferatum*. Conditions favoring fumonisin production appear to include a period of drought during the growing season with subsequent cool, moist conditions during pollination and kernel formation. Three toxins produced by the fungi have been classified as fumonisin B₁ (FB₁), B₂ (FB₂), and B₃ (FB₃). Current evidence suggests that FB₁ and FB₃ are of similar toxicity, whereas FB₂ is relatively nontoxic. Corn grain may commonly contain 1–3 ppm fumonisins, but occasionally some years as much as 20–100 ppm. The toxins are concentrated primarily in molded, damaged, or light test weight corn. Major health effects are seen in Equidae and swine.

Signs in Equidae include apathy, drowsiness, pharyngeal paralysis, blindness, circling, staggering, and recumbency. The clinical course is usually 1–2 days but may be as short as several hours or as long as several weeks. Icterus may be present when the liver is involved. The characteristic lesion is liquefactive necrosis of the white matter of the cerebrum; the necrosis is usually unilateral but may be asymmetrically bilateral. Some horses may have hepatic necrosis similar to that seen in aflatoxicosis. Horses may develop leukoencephalomalacia from prolonged exposure to as little as 8–10 ppm fumonisins in the diet, and onset of neurologic signs almost invariably leads to death.

Fumonisin has also been reported to cause acute epidemics of disease in weanling or adult pigs, characterized by pulmonary edema and hydrothorax. **Porcine pulmonary edema (PPE)** is usually an acute, fatal disease and appears to be caused by pulmonary hypertension with transudation of fluids in the thorax, resulting in interstitial pulmonary edema and hydrothorax. Acute PPE results after consumption of fumonisins for 3–6 days at dietary concentrations >100 ppm. Morbidity within a herd may be >50%, and mortality among affected pigs is 50%–100%. Signs include acute onset of dyspnea, cyanosis of mucous membranes, weakness, recumbency, and death, often within 24 hr after the first clinical signs. Affected sows in late gestation that survive acute PPE may abort within 2–3 days, presumably as a result of fetal anoxia. Prolonged exposure of pigs to sublethal concentrations of fumonisins results in hepatotoxicosis characterized by reduced growth, icterus, and increased serum levels of cholesterol, bilirubin, AST, lactate dehydrogenase, and γ -glutamyltransferase.

The biochemical mechanism of action for PPE or liver toxicosis is believed to be due to the ability of fumonisins to interrupt sphingolipid synthesis in many animal species, and fatalities result from disturbances in cardiopulmonary dynamics leading to acute pulmonary edema.

Cattle, sheep, and poultry are considerably less susceptible to fumonisins than are horses or swine. Cattle and sheep tolerate fumonisin concentrations of 100 ppm with little effect. Dietary concentrations of 150–200 ppm cause inappetence, weight loss, and mild liver damage. Poultry are affected by concentrations of >200–400 ppm and may develop inappetence, weight loss, and skeletal abnormalities.

No effective treatment is available. Avoidance of moldy corn is the only prevention, although this is difficult because the corn may not be grossly moldy or may be contained in a mixed feed. However, most of the toxin is present in broken or small, poorly formed kernels. Cleaning grain to remove the screenings markedly reduces fumonisin concentration. Corn suspected of containing fumonisins should not be given to horses. Binding of fumonisins with glucose has been demonstrated to alleviate or eliminate toxicosis in pigs, but development of the process on a commercial scale has not yet been accomplished. Advisory exposure guidelines by the FDA have recommended total dietary concentrations (ppm) as follows: horses <1, swine <10, ruminants <30, poultry <50, breeding ruminants and poultry <15 ppm.

MYCOTOXIC LUPINOSIS

Lupines (*Lupinus* spp) cause two distinct forms of poisoning in livestock: lupine poisoning and lupinosis. The former is a nervous syndrome caused by alkaloids present in bitter lupines; the latter is a mycotoxic disease characterized by liver injury and jaundice, which results mainly from the feeding of sweet lupines. Lupinosis is important in Australia and South Africa and also has been reported from New Zealand and Europe. There is increasing use of sweet lupines, either as forage crops or through feeding of their residues after grain harvest, as strategic feed for sheep in Mediterranean climate zones. Sheep, and occasionally cattle and horses, are affected, and pigs are also susceptible.

Etiology and Pathogenesis: The causal fungus is *Phomopsis leptostromiformis*, which causes *Phomopsis* stem-blight, especially in white and yellow lupines; blue varieties are resistant. It produces sunken, linear stem lesions that contain black, stromatic masses, and it also affects the pods and seeds. The fungus is also a saprophyte and grows well on dead lupine material (eg, haulm, pods, stubble) under favorable conditions. It produces phomopsins as secondary metabolites on infected lupine material, especially after rain.

Clinical Findings, Lesions, and Diagnosis: Clinical changes are mainly attributable to toxic hepatocyte injury, which causes mitotic arrest in metaphase, isolated cell necrosis, and hepatic enzyme leakage, with loss of metabolic and excretory function.

Early signs in sheep and cattle are inappetence and listlessness. Complete anorexia and jaundice follow, and ketosis is common. Cattle may show lacrimation and salivation. Ketosis is a common sequela in pregnant cattle or recently calved cows. Survivors may develop hepatic cirrhosis. Sheep may become photosensitive, and a skeletal muscle myopathy can develop. As disease progresses, liver failure may cause hepatoencephalopathy characterized by stumbling, disorientation, and recumbency before death. In acute outbreaks, deaths occur in 2–14 days.

In acute disease, icterus is marked. Livers are enlarged, orange-yellow, and fatty. More chronic cases show bronze- or tan-colored livers that are firm, contracted in size, and fibrotic. Copious amounts of transudates may be found in the abdominal and thoracic cavities and in the pericardial sac. Some animals may have spongiform lesions in the brain.

Feeding of moldy lupine material, together with clinical signs and increased levels of serum liver enzymes, strongly indicate lupinosis.

Control: Frequent surveillance of sheep and of lupine fodder material for characteristic black spot fungal infestation, especially after rains, is advised. The utilization of lupine cultivars, bred and developed for resistance to *P leptostromiformis*, is advocated. Oral doses of zinc (≥ 0.5 g/day) have protected sheep against liver injury induced by phomopsins.

PASPALUM STAGGERS

This incoordination results from eating paspalum grasses (*Paspalum* spp) infested by *Claviceps paspali*. The life cycle of this fungus is similar to that of *C purpurea* (see p 3012). Toxic infestations are most likely after humid, wet summers. The yellow-gray sclerotia, which mature in the seed heads in autumn, are round, roughened, and 2–4 mm in diameter. Ingestion of sclerotia causes nervous signs in cattle most commonly, but horses and sheep also are susceptible. Guinea pigs can be affected experimentally. The toxicity is not ascribed to ergot alkaloids; the toxic principles are thought to be paspalinine and paspalitrem A and B, tremorgenic compounds from the sclerotia.

A sufficiently large single dose causes signs that persist for several days. Animals display continuous trembling of the large muscle groups; movements are jerky and incoordinated. If they attempt to run, they fall over in awkward positions. Appetite

remains good, and animals will eat if feed is provided. Affected animals may be belligerent and dangerous to approach or handle. After prolonged exposure, condition is lost and complete paralysis can occur. The time of onset of signs depends on the degree of the infestation of seed heads and the grazing habits of the animals. Experimentally, early signs appear in cattle after sclerotia at ~ 100 g/day has been administered for >2 days. Although the mature ergots are toxic, they are most dangerous just when they are maturing to the hard, black (sclerotic) stage.

Medical treatment is usually not necessary, unless animals have physical injuries or are compromised from dehydration or lack of eating. Recovery follows removal of the animals to feed not contaminated with sclerotia of *C paspali*. Animals are less affected if left alone and provided readily available nutritious forages. Care should be taken to prevent accidental access to ponds or rough terrain where accidental trauma or drowning could occur. Topping of the pasture to remove affected seed heads has been effective in control.

SLAFRAMINE TOXICOSIS

Trifolium pratense (red clover) may become infected with the fungus *Rhizoctonia leguminicola* (black patch disease), especially in wet, cool years. Rarely, other legumes (white clover, alsike, alfalfa) may be infected. Slaframine is an indolizidine alkaloid recognized as the toxic principle, and it is stable in dried hay and probably in silage. Horses are highly sensitive to slaframine, but clinical cases occur in cattle as well. Profuse salivation (salivary syndrome) develops within hours after first consumption of contaminated hay; signs also include mild lacrimation, diarrhea, mild bloat, and frequent urination. Morbidity can be high, but death is not expected, and removal of contaminated hay allows recovery and return of appetite within 24–48 hr. A related alkaloid, swainsonine, produced by *R leguminicola*, has caused a lysosomal storage disease from prolonged exposure, but its importance in the salivary syndrome is not confirmed. Diagnosis is tentatively based on recognition of the characteristic clinical signs and the presence of “black patch” on the forages. Chemical detection of slaframine or swainsonine in forages helps to confirm the diagnosis. There is no specific antidote to slaframine toxicosis, although atropine may control at least some of the prominent

salivary and GI signs. Removal of animals from the contaminated hay is essential. Prevention of *Rhizoctonia* infection of clovers has been difficult. Some clover varieties may be relatively resistant to black patch disease. Reduced usage of red clover for forages or dilution with other feeds is helpful.

TRICOTHECENE TOXICOSIS

The trichothecene mycotoxins are a group of closely related secondary metabolic products of several families of imperfect or plant pathogenic fungi. Those of most importance in much of the world are produced species of *Fusarium*, but also from genera of *Trichothecium*, *Myrothecium*, *Cephalosporium*, *Stachybotrys*, *Trichodesma*, *Cylindrocarpum*, and *Verticimonosporium*. Trichothecenes are classified as nonmacrocyclic (eg, deoxynivalenol [DON] or vomitoxin, T-2 toxin, diacetoxyscirpenol [DAS], and others) or macrocyclic (eg, satratoxin, rosidin, verrucarins). For livestock, the most important trichothecene mycotoxin is DON, which is commonly a contaminant of corn, wheat, and other commodity grains. Lesser amounts of T2 toxin and DAS are found sporadically in the same sources.

The trichothecene mycotoxins are highly toxic at the subcellular, cellular, and organic system level. Trichothecenes inhibit protein synthesis by affecting ribosomes to interfere with protein synthesis and covalently bond to sulfhydryl groups.

Toxicity of T-2 toxin and DAS is based on direct cytotoxicity and is often referred to as a radiomimetic effect (eg, bone marrow hypoplasia, gastroenteritis, diarrhea, hemorrhages). Direct contact with skin and oral cavity causes irritation and ulceration. Stomatitis, hyperkeratosis with ulceration of the esophageal portion of the gastric mucosa, and necrosis of the GI tract have been seen after ingestion of trichothecenes. Systemic effects of T-2 and DAS are often self-limiting because of oral irritation and feed refusal.

Given in sublethal toxic doses via any route, the trichothecenes are immunosuppressive in mammals; however, longterm feeding of high levels of T-2 toxin does not seem to activate latent viral or bacterial infections. The toxins may affect function of helper T cells, B cells, or macrophages, or the interaction among these cells.

Irritation of the skin and mucous membranes and gastroenteritis are another set of signs typical of trichothecene toxicosis. Hemorrhagic diathesis can occur, and the

radiomimetic injury (damage to dividing cells) is expressed as lymphopenia or pancytopenia. Eventually, hypotension may lead to death. Many of the severe effects described for experimental trichothecene toxicosis are due to dosing by gavage. From a practical perspective, high concentrations of trichothecenes often cause feed refusal and therefore are often self-limiting as a toxic problem.

Because of the immunosuppressive action of trichothecenes, secondary bacterial, viral, or parasitic infections may mask the primary injury. The lymphatic organs are smaller than normal and may be difficult to find on necropsy.

Refusal to consume contaminated feedstuffs is the typical sign, which limits development of other signs. If no other food is offered, animals may eat reluctantly, but in some instances, excessive salivation and vomiting may occur. In the past, the ability to cause vomiting had been ascribed to DON only (hence the common name vomitoxin). However, other members of the trichothecene family also can induce vomiting.

In North America and many other parts of the world, DON is a substantial concern because of its common occurrence in feed grains and its well-known ability to cause feed refusal. Swine appear to be most sensitive to feed refusal, with greater tolerance by horses and dogs and even higher acceptance by ruminants.

In swine, reduced feed intake may occur at dietary concentrations as low as 1 ppm, and refusal may be complete at 10 ppm. Ruminants generally will readily consume as much as 10 ppm dietary vomitoxin, and beef cattle have tolerated 12–20 ppm in some circumstances. Poultry may tolerate as much as 100 ppm. Horses may accept as much as 35–45 ppm dietary DON without feed refusal or adverse clinical effects. Dogs also will refuse foods containing DON, usually at concentrations >5 ppm. Related effects of weight loss, hypoproteinemia, and weakness may follow prolonged feed refusal. There is little evidence that DON causes reproductive dysfunction in domestic animals. Experimental studies suggest that DON may cause variable effects of immunosuppression or immunostimulation, but research is continuing to define whether DON has a practical role in disease susceptibility in field conditions.

Feed refusal caused by DON is a learned response known as taste aversion. The major effect of DON is feed refusal; it is rarely if ever a cause of the trichothecene effects described above. It appears related

to brain neurochemical changes in serotonin, dopamine, and 5-hydroxy-indoleacetic acid. Feed refusal response to DON varies widely among species. DON in swine causes conditioned taste aversion, and swine appear to recognize new flavors (eg, flavoring agents) added to DON-containing feed and thus develop aversion to the new taste as well. Once uncontaminated feed is provided, animals usually resume eating within 1–2 days. A less well-known mycotoxin, fusaric acid, appears to interact with DON in the neurochemical response, leading to feed refusal.

Confirmation of increased levels of DON by analysis in a ration is often used to confirm DON-related feed refusal or to judge the fitness of a feed ingredient. However, some mycotoxins may be "masked" or undetected by routine assay methods. These conjugated mycotoxins may escape detection and not provide adequate warning of feed refusal levels. Use of binders for DON mycotoxin is currently an active area of research. Currently, the aluminosilicates effective for aflatoxins appear not to be useful against DON. Glucomannan yeast-derived adsorbents may have potential to improve some aspects of DON feed refusal in swine, but work is ongoing to clarify use of this category of detoxicants. DON has been removed from barley by an abrasive pearling procedure, which removed two-thirds of DON with loss of only 15% of the grain mass. This and other forms of cleaning grain may prove useful to decrease DON when alternative grain is not available. In addition, diverting grain from swine to the more tolerable ruminants is an alternative as well.

Macrocytic trichothecene-related diseases have received a number of specific names. The best known is **stachybotryotoxicosis** of horses, cattle, sheep, pigs, and poultry, first diagnosed in the former USSR but occurring also in Europe and South Africa. Cutaneous and mucocutaneous lesions, panleukopenia, nervous signs, and

abortions have been seen. Death may occur in 2–12 days.

Myrotheciotoxicosis and dendrochiotoxicosis have been reported from the former USSR and New Zealand. The signs resemble those of stachybotryotoxicosis, but death may occur in 1–5 days.

Diagnosis: Because the clinical signs are nonspecific, or masked by secondary infections and disease, diagnosis is difficult. Analysis of feed is often costly and time consuming but ideally should be attempted. Interim measures are carefully examining feedstuffs for signs of mold growth or caking of feed particles and switching to an alternative feed supply. Change of feed supply often results in improvement and thus may provide one more clue that the original feed was contaminated.

Control: Symptomatic treatment and feeding of uncontaminated feed are recommended. Steroidal antishock and anti-inflammatory agents, such as methylprednisolone, prednisolone, and dexamethasone, have been used successfully in experimental trials. Poultry and cattle are more tolerant of trichothecenes than are pigs. Pigs exposed to DON often recover appetite promptly when uncontaminated feed is offered.

DON-contaminated feed treated with various adsorbents, including calcium aluminosilicates, bentonite, sodium bisulfite, and yeast-based glucomannans have not been helpful to correct feed refusal in swine. Addition of 0.2% glucomannan mycotoxin adsorbent to DON-contaminated diet for pregnant sows increased percentage of pigs born live but did not correct reduced feed intake. Physical seed treatment (abrasive pearling procedure) has removed two-thirds of DON from barley. In general, cleaning and removal of damaged grain (screenings) improves feed quality and acceptance of mycotoxin-contaminated grains.

SMOKE INHALATION

Smoke inhalation caused by fires is a major cause of fatalities in animals. It usually involves inhalation of a complex mixture of toxicologic agents and pyrolysis products. Injury typically results from a combination

of thermal injury to the upper airways, oxygen deprivation, and toxicity from inhaled materials. Smaller animals and in particular birds are usually more susceptible to inhaled toxicants because of their

greater respiratory minute volume per unit mass and relatively larger respiratory surface area per unit mass.

Etiology: Important agents involved in smoke inhalation include thermal injury, soot, carbon monoxide, cyanide gas, nitrogen, methane, oxides of nitrogen (NO_x), zinc oxide, phosphorus, sulfur trioxide, titanium tetrachloride, oil fog, Teflon® particles, and Teflon® pyrolysis products (polymer fume fever). Nitrogen and methane are not especially toxic; however, they are important in fires because they dilute oxygen in the breathable atmosphere.

Inhalation thermal injury can occur without obvious external injuries and be relatively slow to manifest, so it is often clinically underestimated. Airway compromise generally peaks 12–24 hr after initial injury. Except for steam inhalation and possibly inhalation of particles with continuing pyrolysis, inhalation thermal injuries are usually confined to the upper airways because of their large heat capacitance. Burns of the upper airway typically induce upper airway edema. Loss of oncotic pressure and fluid resuscitation can exacerbate these effects. Inhalation of steam typically produces severe lung injuries.

Carbonaceous soot particles are not especially toxic in themselves. However, they act as carriers of other toxicants adsorbed onto the surfaces of soot particles. This results in increased toxicant exposure and, depending on particle size, deeper penetration of toxicants into the respiratory system. The degree and site of damage depends on particle size, particle surface area, solubility, concentration, duration of exposure, and rate of particle clearance. Large, chemically reactive and irritating particles tend to affect the upper airways and are cleared quickly, whereas smaller, low-solubility particles tend to affect the deeper respiratory structures and are cleared more slowly.

Important inhaled blood agents/asphyxiants that disrupt tissue oxygen delivery or utilization include cyanide, carbon monoxide, nitrogen, and methane. Cyanide inhalation is extremely common with smoke inhalation. Essentially, pyrolysis of most nitrogen-containing materials (eg, nitrocellulose, nylon, wool, silk, asphalt, polyurethane, and many plastics) will liberate cyanide. Cyanide is a rapidly acting histotoxic agent that inhibits mitochondrial cytochrome c oxidase, resulting in the arrest of aerobic metabolism. (See also CYANIDE POISONING, p 2959.)

Carbon monoxide poisoning is ubiquitous after smoke inhalation. Carbon monoxide is produced by the incomplete combustion of any organic material. Carbon monoxide binds to hemoglobin to form carboxyhemoglobin, which cannot carry oxygen and, therefore, results in tissue hypoxia. A visible flame is not necessary for carbon monoxide poisoning, and gas appliances can liberate large amounts of it. Epizootics of fatal carbon monoxide poisoning classically occur during periods of cold weather, particularly after an electrical outage.

NO_x have low water solubility, and low concentrations generally cause delayed pulmonary irritation. Also, compared with other agents, the NO_2 present in NO_x reacts relatively slowly with respiratory secretions, forming nitrous (HNO_2) and nitric (HNO_3) acid. The end result is delayed chemical pneumonitis and pulmonary edema. These features often result in delayed clinical recognition of NO_x injuries.

Zinc oxide fumes are a classical cause of metal fume fever and are formed when zinc or zinc alloys (eg, galvanized metals, brass) are heated. Metal fume fever is a classical cytokine cascade acute phase-like response. Notably, tolerance to zinc oxide fumes develops rapidly but is also quickly lost.

Phosphorous, titanium tetrachloride, and sulfur trioxide fumes are notoriously irritating. Titanium tetrachloride releases hydrochloric acid in contact with water in respiratory secretions. Inhaled sulfur trioxide forms sulfuric acid when it contacts respiratory secretions. Smoke machines that atomize mineral oils can produce an oil mist that is mildly irritating to the respiratory system and may trigger underlying respiratory conditions.

Inhalation of PTFE (Teflon®) fumes triggers acute malaise, fever, and respiratory irritation (polymer fume fever). It can result in severe chemical pneumonitis and is notoriously lethal for caged birds. In addition to overheated cooking ware, Teflon® fume fever has been caused by burning of hair spray, dry lubricants, and water-proofing sprays.

Clinical Findings: The most important aspects of the history are duration of exposure, the circumstances of exposure (eg, enclosed versus open spaces), amount of smoke inhaled, severity of injury to other animals, and the sources of the smoke (ie, what toxicants are likely to have been present in the smoke). Unfortunately, this type of information is rarely available. Exposure to smoke in an enclosed space,

prolonged entrapment, carbonaceous oculonasal discharges, a history of resuscitation, evidence of respiratory distress, and altered consciousness all indicate a higher risk of serious lung damage. Preexisting respiratory diseases (eg, COPD) will likely increase the severity of injury.

Clinically serious smoke inhalation often occurs in the absence of obvious external physical injury. However, facial burns, oropharyngeal blistering and/or edema, changed voice, stridor, coughing, upper airway mucosal lesions, and carbonaceous discharges may be present. Evidence of lower respiratory tract injury such as tachypnea, dyspnea, cough, decreased breath sounds, wheezing, rales, rhonchi, and retractions may be present. Both upper and lower respiratory injury may be relatively slow to develop and may peak 12–24 hr or even later after exposure. There is always a substantial risk of delayed airway obstruction secondary to upper airway edema for at least 24–48 hr after initial injury. Lack of apparent injury immediately after smoke inhalation should not reduce the level of clinical suspicion.

In general, evidence of asphyxiant exposure commonly includes CNS depression, changes in affect, lethargy, generalized muscle weakness, and obtundation. Neurologic injury secondary to hypoxia, often permanent, is common under these circumstances. Coma after smoke inhalation is most commonly caused by severe carbon monoxide poisoning and the ensuing hypoxia. The prognosis is poor.

The onset of zinc oxide fume fever is typically delayed by 4–8 hr after exposure. Common clinical signs include general malaise, cough, sternal pain, voice changes, and fever. Typically, these signs are self-limiting, and recovery is rapid unless high levels of exposure have occurred. In these cases, there is often an apparent period of recovery followed by onset of dyspnea and respiratory distress 24–36 hr later.

Polymer (Teflon®) fume fever typically presents as general malaise, cough, sternal pain, voice changes, and fever. Severe lung injuries are common in birds, and sudden death is a common outcome.

Diagnosis: Important diagnostic techniques include laryngoscopy/bronchoscopy, pulse oximetry/co-oximetry, arterial blood gases, carboxyhemoglobin level determination, lactate level determination, CBCs, chest imaging, electrocardiography, and pulmonary function testing.

Bronchoscopy and laryngoscopy are the gold standard methods to diagnose and assess smoke inhalation. Bronchoscopy is the single most reliable method to establish the diagnosis and extent/severity of injury. It is generally superior to and more accurate than other diagnostic methods (including clinical examination). Classic findings include severe subglottic injury, erythema, charring, deposition of soot, edema, and/or mucosal ulceration.

Ordinary pulse oximetry (two wavelengths) is inaccurate when carboxyhemoglobin and/or methemoglobin are present. Both situations will generate falsely high pulse oximetry readings that are not reflective of the degree of underlying disease. Pulse co-oximetry (four or five wavelengths) is more reliable in these situations.

PaO₂ is a poor indicator of carbon monoxide poisoning and/or cellular hypoxia, because it reflects the amount of oxygen dissolved in blood. This is not altered in carbon monoxide poisoning, because the dissolved oxygen is a small fraction of total arterial blood oxygen content. Because blood gas machines usually calculate oxygen saturation based on PaO₂, this measurement will also be inaccurate.

Blood carboxyhemoglobin measurements may underestimate the actual level of exposure if oxygen has been administered before sample collection. Additionally, there is a poor correlation between carboxyhemoglobin level and the ultimate neurologic outcome in cases of significant poisoning.

Metabolic acidosis and increased lactate is common when hypoxia, carboxyhemoglobin, cyanide poisoning, methemoglobinemia, and trauma are present. Very high blood lactate levels are typical in acute cyanide poisoning. Given the usually slow turnaround time associated with cyanide measurements, high levels of blood lactate combined with a history of smoke inhalation provide a strong index of suspicion of cyanide poisoning. Cyanide measurements are strongly correlated with exposure and toxicity levels.

Clinically significant smoke inhalation is often associated with declines in hemoglobin and PCV approximately 1 wk after exposure.

Pulmonary radiographic changes after smoke inhalation typically develop 24–36 hr after exposure. An initially clear chest radiograph does not exclude significant lung injury after smoke inhalation. Repeat imaging at 24–36 hr after exposure typically

demonstrates radiographic signs consistent with atelectasis, pulmonary edema, and hyperinflation. Depending on the agents involved, late radiographic changes may reflect fibrosis and bronchiolitis obliterans.

CT changes typically develop earlier than chest radiographic changes and classically consist of peribronchial ground-glass opacities and peribronchial consolidations. Brain CT findings may demonstrate cerebral hypoxia-associated ischemia and injuries to the globus pallidus, which are nearly pathognomonic for carbon monoxide poisoning.

Treatment, Control, and Prevention:

Treatment involves maintenance of the airway, aggressive management of acute respiratory distress, antidote treatment if warranted, suppression of inflammation, and prevention of secondary infections with broad spectrum antibiotics. Severe carbon monoxide poisoning combined with significant smoke inhalation is almost uniformly fatal in people; thus, euthanasia should be considered early in the treatment and assessment processes.

Maintenance of the airway either by endotracheal intubation or tracheostomy is often critical given that severe upper airway edema may occur. It is often better to intubate earlier in the disease progression, because delayed airway edema may subsequently make intubation difficult or impossible.

Carbon monoxide poisoning should always be assumed to have occurred in all individuals with smoke inhalation. The mainstay of treatment is oxygen supplementation.

Some degree of cyanide poisoning should also be assumed in almost all cases of smoke inhalation. Induction of methemoglobinemia

is not recommended in cases of smoke inhalation because of the risk of further reducing oxygen-carrying capacity of the blood in the presence of carboxyhemoglobinemia. Because of its efficacy, ease of administration, and low toxicity, hydroxocobalamin administration is currently recommended in cases of smoke inhalation. Hydroxocobalamin can be combined with thiosulfate administration. Data are limited on the effectiveness of thiosulfate alone; however, it is useful in cyanide poisoning and will not compromise oxygen-carrying capacity of the blood (ie, unlikely to cause harm and may be beneficial).

Methemoglobinemia after smoke inhalation is uncommon and can be managed with methylene blue treatment if required.

Notably, *N*-acetylcysteine has been effective for the treatment of polymer fume fever. Chest physiotherapy is regarded as being beneficial. Low tidal volume positive-pressure ventilation (PEEP) and high-frequency percussive ventilation (HFPV) have been demonstrated to increase short-term survival in people but are rarely available in veterinary practice.

Bronchodilation with a β_2 -agonist (eg, albuterol, terbutaline, epinephrine) is an important aspect of treatment, because smoke induces bronchospasm and bronchoconstriction. When combined with airway edema, these effects contribute to airway obstruction.

The effectiveness of corticosteroids after smoke inhalation is contentious. Corticosteroids are notably beneficial in cases of metal fume fever.

Control and prevention of smoke inhalation involves avoidance of exposure, adequate ventilation if smoke is likely to be present, and use of smoke detection systems.

TOXICITIES FROM HUMAN DRUGS

TOXICITIES FROM OVER-THE-COUNTER DRUGS

Human drugs or nutritional supplements available without a prescription are known as over-the-counter (OTC) medications. Exposures to OTC drugs in pets can be accidental or intentional. A valid client-patient-veterinarian relation-

ship must exist for veterinarians to recommend extra-label use of these drugs to their clients. Most are not approved for veterinary use by the FDA, and safety of most OTC drugs has not been determined in animals. Veterinarians should understand the potential risks of using OTC medications and communicate these risks to their clients.

COLD AND COUGH MEDICATIONS

Antihistamines

Antihistamines are H_1 -receptor antagonists that provide symptomatic relief of allergic signs caused by histamine release, including pruritus and anaphylactic reactions. They are also used as sedatives and antiemetics. Antihistamines belong to different classes and are categorized as first- or second-generation (also called nonsedating) antihistamines. First-generation antihistamines may cause adverse effects because of their cholinergic activity and ability to cross the blood-brain barrier. Second-generation antihistamines are more lipophobic than first-generation antihistamines and are thought to lack CNS and cholinergic effects at therapeutic doses. Antihistamines are often found in combination with other ingredients (eg, decongestants, analgesics like acetaminophen or NSAIDs) in many OTC cold, sinus, and allergy medications.

Chlorpheniramine is a first-generation propylamine-derivative antihistamine. Oral absorption of chlorpheniramine in dogs is rapid and complete, reaching peak plasma concentrations in 30–60 min. Chlorpheniramine maleate undergoes substantial first-pass effect. Chlorpheniramine and its metabolites are primarily excreted in urine. The recommended dose in cats and dogs is 1–2 mg and 2–8 mg respectively, PO, bid-tid. Mild clinical signs such as depression and GI upset have been reported for dosages <1 mg/kg. Significant clinical signs such as ataxia, tremors, depression or hyperactivity, hyperthermia, and seizures may be seen within 6 hr of ingestion of large amounts.

Clemestine, because of its low oral bioavailability in dogs (3% vs 20%–70% in people), may have limited effectiveness at the recommended dosages of 0.05–0.1 mg/kg, PO, bid; 1.34 mg of clemestine fumarate is equivalent to 1 mg of clemestine. Common adverse effects of clemestine may include sedation, lethargy, and anticholinergic signs (dry mouth, tachycardia, agitation, decreased intestinal secretions/motility).

Dimenhydrinate and diphenhydramine are first-generation ethanolanine-derivative antihistamines. Dimenhydrinate is used for its antiemetic effects and for prevention of motion sickness in dogs and cats. Diphenhydramine is well absorbed orally in people but undergoes first-pass metabolism in the liver with only 40%–60% of the drug reaching the systemic circulation. Peak plasma concentrations of

ethanolanine-derivative antihistamines occur within 1–5 hr; elimination half-lives vary from 2.4–10 hr. A recommended dosage of dimenhydrinate and diphenhydramine in cats and dogs is 4–8 mg/kg and 2–4 mg/kg, respectively. Hyperactivity or depression, hypersalivation, tachypnea, and tachycardia are the most common adverse effects reported with these antihistamines, generally within 1 hr of exposure.

Promethazine hydrochloride is an ethylanino derivative of phenothiazine and first-generation antihistamine used to manage motion sickness. Promethazine is widely distributed in body tissues and readily crosses the placenta. Overdoses may result in CNS depression or excitation. CNS depression was reported in a dog 30 min after ingesting promethazine at 1 mg/kg.

Meclizine is a first-generation piperazine-derivative antihistamine commonly used as an antiemetic. Peak plasma concentrations occur within 2–3 hr of oral administration. Meclizine is primarily excreted as metabolites in urine, with a reported serum half-life of 6 hr. The recommended dose in dogs is 25 mg/day (per dog). When dogs have received meclizine at <33 mg/kg, only mild hyperactivity or depression has been reported.

Loratadine is a tricyclic, long-acting antihistamine with selective peripheral histamine H_1 -receptor antagonist activity. In people, loratadine is well absorbed orally and extensively metabolized to an active metabolite. Most of the parent drug is excreted unchanged in the urine. The mean elimination half-life in people is 8.4 hr. Loratadine appears to have a large margin of safety in animals. The suggested dose in dogs is 5–10 mg, PO, once to twice daily (per dog). No deaths were reported at oral dosages up to 5 g/kg in rats and mice. In rats, mice, and monkeys, no clinical signs were seen at 10 times the maximum recommended human daily oral dose.

Cetirizine, a major metabolite of hydroxyzine, is a piperazine derivative nonsedating antihistamine. It selectively inhibits peripheral H_1 receptors and does not have significant anticholinergic or antiserotonergic effects when used at the recommended dosage. The recommended dosage for histamine-mediated pruritic conditions in dogs is 1 mg/kg, PO, once to twice daily, and 5 mg, PO, bid for cats. The drug appears to be well tolerated in dogs and cats. The minimum lethal dosage is 237 mg/kg in mice and 562 mg/kg in rats. Adverse reactions include vomiting, hypersalivation, sedation, drowsiness, and occasionally hyperactivity.

Treatment: Treatment of antihistamine toxicosis is primarily symptomatic and supportive. Emesis should only be considered in asymptomatic patients. Activated charcoal may be useful for recent ingestion. Symptomatic patients should be watched for anticholinergic signs (agitation, mydriasis, tachycardia, decreased intestinal motility) and treated as needed. Cardiovascular functions (heart rate and blood pressure) and body temperature should be closely monitored. Propranolol (0.02–0.06 mg/kg, IV) can be helpful to treat consistent tachycardia in normotensive patients. Diazepam can be used to control seizures or seizure-type activity. Physostigmine is recommended to counteract the CNS anticholinergic effects of antihistamine overdoses in people, although the risk of seizures associated with this drug may limit its use. IV fluids should be given as needed.

Dextromethorphan

Dextromethorphan is a non sedating, nonaddictive, centrally acting opioid cough suppressant. It is available in many OTC cold and cough medications. At the recommended dosage, it enhances the threshold for coughing. It is rapidly absorbed orally and converts to the active metabolite dextrorphan in the liver. Cough suppressant activity can last 3–12 hr, depending on the formulation. Overdoses can cause CNS and GI effects such as agitation, hallucination, nervousness, mydriasis, shaking, vomiting, or diarrhea. Some clinical signs may be similar to those of serotonin syndrome (agitation, disorientation, hyperthermia, nervousness, shaking). Treatment is mainly supportive care. Diazepam can be used to control some of the CNS effects. Phenothiazine tranquilizers (acepromazine or chlorpromazine) or cyproheptadine (1.1 mg/kg, PO or per rectum, for dogs, and 2–4 mg per cat; repeat once in 6–8 hr if needed) can be given for serotonin syndrome.

DECONGESTANTS

Imidazoline Decongestants

The imidazoline derivatives, **oxymetazoline**, **xylometazoline**, **tetrahydrozoline**, and **naphazoline**, are found in topical ophthalmic and nasal decongestants available OTC. They are generally used as topical vasoconstrictors in the nose and eyes for temporary relief of nasal congestion due to colds, hay fever or other upper respiratory allergies, or sinusitis.

Imidazolines are sympathomimetic agents, with primary effects on α -adrenergic receptors and little if any effect on β -adrenergic receptors. Oxymetazoline is readily absorbed orally. Effects on α -receptors from systemically absorbed oxymetazoline hydrochloride may persist for up to 7 hr after a single dose. The elimination half-life in people is 5–8 hr. It is excreted unchanged both by the kidneys (30%) and in feces (10%).

Clinical Findings: In dogs, signs of intoxication may include vomiting, bradycardia, cardiac arrhythmias, poor capillary refill time, hypotension or hypertension, panting, increased upper respiratory sounds, depression, weakness, collapse, nervousness, hyperactivity, or shaking. These signs usually appear within 30 min to 4 hr after exposure. In general, imidazoline decongestant exposure may affect the GI, cardiopulmonary, and nervous systems.

Treatment: Decontamination (induction of emesis and administration of activated charcoal) may not be practical because of the rapid absorption and onset of clinical signs. Heart rate and rhythm and blood pressure should be assessed, and an ECG obtained if needed. IV fluids should be given, along with atropine at 0.02 mg/kg, IV, if bradycardia is present. Diazepam (0.25–0.5 mg/kg, IV) can be given if CNS signs (eg, apprehension, shaking) are present. Serum electrolytes (ie, potassium, sodium, chloride) should be assessed and corrected as needed. Yohimbine, a specific α_2 -adrenergic antagonist, can also be used at 0.1 mg/kg, IV, and repeated in 2–3 hr if needed. If yohimbine is not available, atipamezole can be used at 50 mcg/kg, one-fourth IV and the rest IM; it can be repeated in 30–60 min if there is no improvement.

Phenylephrine

Phenylephrine is a sympathomimetic amine with mainly an α_1 -adrenergic receptor agonist effect, available OTC as a decongestant in oral formulations (5–10 mg tablets), nasal sprays, or eye drops (0.25%–1%). It has poor oral bioavailability (38%) in people because of a significant first-pass effect and extensive metabolism by monoamine oxidases in the GI tract and liver. The oral LD₅₀ in rats and mice is 350 mg/kg and 120 mg/kg, respectively. The half-life is 2–3 hr. CNS stimulation, agitation, nervousness, and hypertension are possible

but less frequent with phenylephrine than with pseudoephedrine. Treatment is mainly symptomatic care and is similar to that for pseudoephedrine toxicosis (*see below*).

Pseudoephedrine and Ephedrine

Pseudoephedrine is a sympathomimetic drug found naturally in plants of the genus *Ephedra*. Several states in the USA have limited the availability and use of pseudoephedrine as an OTC decongestant because of its use as a precursor in illegal amphetamine synthesis. It is being replaced with other decongestants such as phenylephrine.

Pseudoephedrine is a stereoisomer of ephedrine and is available as the hydrochloride or sulfate salt. Both ephedrine and pseudoephedrine have α - and β -adrenergic agonist effects. The pharmacologic effects of the drugs are due to direct stimulation of adrenergic receptors and the release of norepinephrine.

In people, pseudoephedrine is rapidly absorbed orally. The onset of action is 15–30 min, with peak effects within 30–60 min. With extended-release preparations (12–24 hr), onset of clinical signs can be delayed (2–8 hr) and duration of clinical signs can be longer than with regular preparations. It is incompletely metabolized in the liver. Approximately 90% of the drug is eliminated through the kidneys. Renal excretion is accelerated in acidic urine. Elimination half-life varies between 2–21 hr, depending on urinary pH.

Clinical Findings: Pseudoephedrine and ephedrine overdose can result in mainly sympathomimetic effects, including agitation, hyperactivity, mydriasis, tachycardia, hypertension, sinus arrhythmias, anxiety, tremors, hyperthermia, head bobbing, hiding, and vomiting. Clinical signs can be seen at dosages of 5–6 mg/kg, and death may occur at 10–12 mg/kg.

Treatment: Treatment of pseudoephedrine toxicosis consists of decontamination, controlling the CNS and cardiovascular effects, and supportive care. Vomiting should be induced only in asymptomatic patients, followed by administration of activated charcoal with a cathartic. If the animal's condition contraindicates induction of emesis, a gastric lavage with a cuffed endotracheal tube should be performed. Hyperactivity, nervousness, or seizures can be controlled with acepromazine (0.05–1 mg/kg, IM, IV, or SC), chlorpromazine (0.5–1 mg/kg, IV), phenobarbital

(3–4 mg/kg, IV), or pentobarbital to effect. Diazepam should be avoided, because it can exaggerate hyperactivity. Phenothiazines should be used with caution because they can lower the seizure threshold, lower blood pressure, and cause bizarre behavioral changes. Tachycardia can be controlled with propranolol at 0.02–0.04 mg/kg, IV, repeated if needed, or with esmolol at 0.2–0.5 mg/kg, given slowly IV or as a constant-rate infusion at 25–200 mcg/kg/min. IV fluids should be given. Acidifying the urine with ammonium chloride (50 mg/kg, PO, qid) or ascorbic acid (20–30 mg/kg, IM or IV, tid) may enhance urinary excretion of pseudoephedrine. Acid-base status should be monitored if ammonium chloride or ascorbic acid is given. Electrolytes, heart rate and rhythm, and blood pressure should be monitored. Excessive trembling or shaking can cause myoglobinuria; if this occurs, kidney function should be monitored. Significant and persistent hyperthermia due to severe hyperactivity and CNS excitation could result in disseminated intravascular coagulation. Clinical signs of toxicosis can last 1–4 days. The presence of pseudoephedrine in urine can support the diagnosis.

ANALGESICS

Over-the-Counter Nonsteroidal Anti-inflammatory Drugs

NSAIDs are the most commonly used class of human medications in the world. Because of their widespread availability and use, acute accidental ingestion of human NSAIDs in dogs and cats is quite common. Ibuprofen, aspirin, and naproxen are some of the most commonly encountered NSAIDs in pet animals.

NSAIDs inhibit the enzyme cyclooxygenase (COX; also referred to as prostaglandin synthetase), blocking the production of prostaglandins. It is believed that most NSAIDs act through COX inhibition, although they may also have other mechanisms of action. (*See also* p 2714.)

Ibuprofen, 2-(4-isobutylphenyl) propionic acid, is used for its anti-inflammatory, antipyretic, and analgesic properties in animals and people. It is rapidly absorbed orally in dogs, with peak plasma concentrations seen in 30 min to 3 hr. Presence of food can delay absorption and the time to reach peak plasma concentration. The mean elimination half-life is ~4.6 hr. Ibuprofen is metabolized in the liver to several metabolites, which are mainly excreted in the urine within 24 hr. The major metabolic pathway

is via conjugation with glucuronic acid, sometimes preceded by oxidation and hydroxylation.

Ibuprofen has been recommended in dogs at 5 mg/kg. However, prolonged use at this dosage may cause gastric ulcers and perforations. GI irritation or ulceration, GI hemorrhage, and renal damage are the most commonly reported toxic effects of ibuprofen ingestion in dogs. In addition, CNS depression, hypotension, ataxia, cardiac effects, and seizures can be seen. Ibuprofen has a narrow margin of safety in dogs. Dogs dosed with ibuprofen at 8–16 mg/kg/day, PO for 30 days, showed gastric ulceration or erosions, along with other clinical signs of GI disturbances. An acute single ingestion of 100–125 mg/kg can lead to vomiting, diarrhea, nausea, abdominal pain, and anorexia. Renal failure may follow dosages of 175–300 mg/kg. CNS effects (ie, seizures, ataxia, depression, coma) in addition to renal and GI signs can be seen at dosages >400 mg/kg. Dosages >600 mg/kg are potentially lethal in dogs.

Cats are susceptible to ibuprofen toxicosis at approximately half the dosage required to cause toxicosis in dogs. Cats are especially sensitive, because they have limited glucuronyl-conjugating capacity. Ibuprofen toxicity is more severe in ferrets than in dogs that consume similar dosages. Typical toxic effects of ibuprofen in ferrets involve the CNS, GI, and renal systems.

Aspirin (acetylsalicylic acid), the salicylate ester of acetic acid, is the prototype of salicylate drugs. It is a weak acid derived from phenol. The oral bioavailability of aspirin may vary because of differences in drug formulation. Aspirin reduces prostaglandin and thromboxane synthesis by COX inhibition. Salicylates also uncouple mitochondrial oxidative phosphorylation and inhibit specific dehydrogenases. Platelets are incapable of synthesizing new cyclooxygenase, leading to an effect on platelet aggregation.

Aspirin is rapidly absorbed from the stomach and proximal small intestine in monogastric animals. The rate of absorption depends on gastric emptying, tablet disintegration rates, and gastric pH. Peak salicylate levels are reached 0.5–3 hr after ingestion. Topically applied salicylic acid can be absorbed systemically.

Aspirin is hydrolyzed to salicylic acid by esterases in the liver and, to a lesser extent, in the GI mucosa, plasma, RBCs, and synovial fluid. Salicylic acid is 50%–70% protein bound, especially to albumin. Salicylic acid readily distributes to extracellular fluids and to the kidneys,

liver, lungs, and heart. Salicylic acid is eliminated by hepatic conjugation with glucuronide and glycine. Renal clearance is enhanced by an alkaline urinary pH. There are significant differences in the elimination and biotransformation of salicylates among different species. Plasma half-lives vary from 1–37.6 hr in animals.

Aspirin toxicosis is usually characterized by depression, fever, hyperpnea, seizures, respiratory alkalosis, metabolic acidosis, coma, gastric irritation or ulceration, liver necrosis, or increased bleeding time. Seizures may occur as a consequence of severe intoxication, although the exact cause is unknown.

Cats are deficient in glucuronyl transferase and have a prolonged excretion of aspirin (half-life 37.5 hr). No clinical signs of toxicosis occurred when cats were given aspirin at 25 mg/kg every 48 hr for up to 4 wk. Dosages of 5 grains (325 mg), bid, can be lethal to cats.

Dogs tolerate aspirin better than cats; however, prolonged use can lead to development of gastric ulcers. Regular aspirin at dosages of 25 mg/kg, tid, has caused mucosal erosions in 50% of dogs after 2 days. Gastric ulcers were seen by day 30 in 66% of dogs given aspirin at 35 mg/kg, PO, tid. Similarly, 43% of dogs given aspirin at 50 mg/kg, PO, bid, showed gastric ulcers after 5–6 wk of dosing. Acute ingestion of 450–500 mg/kg can cause GI disturbances, hyperthermia, panting, seizures, or coma. Alkalosis due to stimulation of the respiratory center can occur early in the course of intoxication. Metabolic acidosis with an increased anion gap usually develops later.

Naproxen, a propionic acid-derivative NSAID, is available OTC as an acid or the sodium salt. It is available as tablets or gel caps (200–550 mg) or as a suspension (125 mg/5 mL). Structurally and pharmacologically, naproxen is similar to carprofen and ibuprofen. In people and dogs, it is used for its anti-inflammatory, analgesic, and antipyretic properties.

Oral absorption of naproxen in dogs is rapid, with peak plasma concentration reached in 0.5–3 hr. The reported elimination half-life in dogs is 34–72 hr. Naproxen is highly protein bound (>99%). In dogs, naproxen is primarily eliminated through the bile, whereas in other species, the primary route of elimination is through the kidneys. The long half-life of naproxen in dogs appears to be because of its extensive enterohepatic recirculation.

Several cases of naproxen toxicosis in dogs have been reported. Dosages of

5.6–11.1 mg/kg, PO, for 3–7 days have caused melena, frequent vomiting, abdominal pain, perforating duodenal ulcer, weakness, stumbling, pale mucous membranes, regenerative anemia, neutrophilia with a left shift, increased BUN and creatinine, and decreased total protein. Acute toxicity from a single oral dose of 35 mg/kg has been reported. Cats may be more sensitive to naproxen toxicity than dogs because of their limited glucuronyl-conjugating capacity.

Treatment: Treatment of NSAID toxicosis consists of early decontamination, protection of the GI tract and kidneys, and supportive care. Vomiting should be induced in recent exposures, followed by administration of activated charcoal with a cathartic. Activated charcoal can be repeated in 6–8 hr to prevent NSAID reabsorption from enterohepatic recirculation. Use of H_2 -receptor antagonists (ranitidine, famotidine, cimetidine) may not prevent GI ulcers but can be useful in treating them. Omeprazole, a proton-pump inhibitor used to inhibit gastric acid secretions, can be used instead of an H_2 blocker at 0.5–1 mg/kg/day, PO, in dogs. Sucralfate (dogs: 0.5–1 g, PO, bid-tid; cats: 0.25–0.5 tablet, PO, bid-tid) reacts with hydrochloric acid in the stomach and forms a paste-like complex that binds to the proteins in ulcers and protects them from further damage. Because sucralfate requires an acidic environment, it should be given ≥ 30 min before administering H_2 antagonists. Misoprostol (dogs: 1–3 mcg/kg, PO, tid) has been shown to prevent GI ulceration when used concomitantly with aspirin and other NSAIDs.

IV fluids should be given at a diuretic rate if the potential for renal damage exists. Alkalinization of the urine with sodium bicarbonate results in ion trapping of salicylates in kidney tubules and can increase their excretion. However, ion trapping should be used judiciously and only in cases when the acid-base balance can be monitored closely. Baseline renal function should be monitored and rechecked at 24, 48, and 72 hr. Prognosis depends on the dose ingested and how soon the animal receives treatment after exposure.

Acetaminophen

Acetaminophen is a synthetic nonopioid derivative of p-aminophenol widely used in people for its antipyretic and analgesic properties. Its use has largely replaced

salicylates because of the reduced risk of gastric ulceration.

Acetaminophen is rapidly absorbed from the GI tract. Peak plasma concentrations are usually seen within an hour but can be delayed with extended-release formulations. It is uniformly distributed into most body tissues. Protein binding varies from 5%–20%. The metabolism of acetaminophen involves two major conjugation pathways in most species. Both involve cytochrome P450 metabolism, followed by glucuronidation or sulfation.

Cats are more sensitive to acetaminophen toxicosis, because they are deficient in glucuronyl transferase and therefore have limited capacity to glucuronidate this drug. In cats, acetaminophen is primarily metabolized via sulfation; when this pathway is saturated, toxic metabolites are produced. In dogs, signs of acute toxicity are usually not seen unless the dosage of acetaminophen exceeds 100 mg/kg. Clinical signs of methemoglobinemia have been reported in 3 of 4 dogs at 200 mg/kg. Toxicity can be seen at lower dosages with repeated exposures. In cats, toxicity can occur with 10–40 mg/kg.

Methemoglobinemia and hepatotoxicity characterize acetaminophen toxicosis. Renal injury is also possible. Acute keratoconjunctivitis sicca has been reported in some dogs after acetaminophen ingestion. Cats primarily develop methemoglobinemia within a few hours, followed by Heinz body formation. Methemoglobinemia makes mucous membranes brown or muddy in color and is usually accompanied by tachycardia, hyperpnea, weakness, and lethargy. Other clinical signs of acetaminophen toxicity include depression, weakness, hyperventilation, icterus, vomiting, hypothermia, facial or paw edema, cyanosis, dyspnea, hepatic necrosis, and death. Liver necrosis is more common in dogs than in cats. Liver damage in dogs is usually seen 24–36 hr after ingestion. Centrilobular necrosis is the most common form of hepatic necrosis seen with acetaminophen toxicity.

Treatment: The objectives of treating acetaminophen toxicosis are early decontamination, prevention or treatment of methemoglobinemia and hepatic damage, and provision of supportive care. A Schirmer tear test (to confirm keratoconjunctivitis) can be used if necessary. Induction of emesis is useful when performed early. This should be followed by administration of activated charcoal with a cathartic. Activated

charcoal may be repeated, because acetaminophen undergoes some enterohepatic recirculation.

Administration of *N*-acetylcysteine (NAC), a sulfur-containing amino acid, can reduce the extent of liver injury or methemoglobinemia. NAC provides sulfhydryl groups, directly binds with acetaminophen metabolites to enhance their elimination, and serves as a glutathione precursor. It is available as a 10% or 20% solution. The loading dose is 140 mg/kg of a 5% solution IV or PO (diluted in 5% dextrose or sterile water), followed by 70 mg/kg, PO, qid for generally seven or more treatments (some authors recommend up to 17 doses). Vomiting can occur with oral NAC. NAC is not labeled for IV use; however, it can be administered as a slow IV (over 15–20 min) with a 0.2-micron bacteriostatic filter. Activated charcoal and oral NAC should be administered 2 hr apart, because activated charcoal could adsorb NAC.

Liver enzymes should be monitored and rechecked at 24 and 48 hr. The animal should also be monitored for methemoglobinemia, Heinz body anemia, and hemolysis. Fluids and blood transfusions should be given as needed. Ascorbic acid (30 mg/kg, PO or injectable, bid-qid) may further reduce methemoglobin levels. Cimetidine (5–10 mg/kg, PO, IM, or IV), a cytochrome P450 inhibitor, may help reduce formation of toxic metabolites and prevent liver damage in dogs only. Cimetidine should not be used in cats. In vitro evidence indicates that use of cimetidine in cats can produce more toxic metabolites of acetaminophen. *S*-Adenosyl methionine has been suggested as an adjunct to manage acute or chronic hepatic injury at 18 mg/kg, PO, for 1–3 mo in dogs and cats.

GASTROINTESTINAL DRUGS

H₂-Receptor Antagonists

H₂-receptor antagonists are structural analogues of histamine, commonly used to treat GI ulcers, erosive gastritis, esophagitis, and gastric reflux. They act at the H₂ receptors of parietal cells to competitively inhibit histamine, reducing gastric acid secretions during basal conditions and when stimulated by food, amino acids, pentagastrin, histamine, or insulin. Cimetidine, famotidine, nizatidine, and ranitidine are examples of this group, also commonly referred to as H₂ blockers. These drugs are rapidly absorbed, reaching peak plasma concentrations within 1–3 hr.

Ranitidine is widely distributed throughout the body. H₂ blockers are primarily metabolized in the liver. Nizatidine, famotidine, and ranitidine are excreted in the urine as metabolites and unchanged drug, whereas cimetidine is eliminated in feces. The elimination half-life for these drugs is short (~2.2 hr). Because cimetidine may inhibit the hepatic microsomal enzyme system, ingestion of an H₂ blocker may result in reduced metabolism of certain drugs, including β blockers, calcium channel blockers, diazepam, metronidazole, and theophylline.

H₂ blockers have a wide margin of safety, with acute oral overdoses typically resulting in minor effects such as vomiting, diarrhea, anorexia, and dry mouth. Serious adverse effects, such as tremors, hypotension, and bradycardia, are more likely to occur with IV H₂-blocker overdoses. The minimum lethal dose of famotidine in dogs is >2 g/kg, PO, and 300 mg/kg, IV. Single oral doses of nizatidine at 800 mg/kg in dogs were not lethal. Most exposures require only monitoring for development of GI signs and supportive care, although massive overdoses may also warrant decontamination.

Antacids

Antacids come in pill and liquid forms and are frequently used to treat GI upset. Common antacids include calcium carbonate, aluminum hydroxide, and magnesium hydroxide (milk of magnesia). These agents are poorly absorbed orally. Calcium- and aluminum-containing antacids generally cause constipation, whereas magnesium-containing antacids tend to cause diarrhea. Some products contain both aluminum and magnesium salts in an attempt to balance their constipating and laxative effects. Acute single ingestion of calcium salts may cause transient hypercalcemia but is unlikely to be associated with significant systemic effects. Induction of emesis within 2–3 hr of exposure may help prevent severe GI upset.

MULTIVITAMINS AND IRON

The common ingredients in multivitamins include ascorbic acid (vitamin C), cyanocobalamin (vitamin B₁₂), folic acid, thiamine (vitamin B₁), riboflavin (vitamin B₂), niacin (vitamin B₃), biotin, pantothenic acid, pyridoxine (vitamin B₆), calcium, phosphorus, iodine, iron, magnesium, copper, zinc, and vitamins A, D, and E. Among these ingredients, iron and vitamins

A and D may cause significant systemic signs. Acute ingestion of other listed ingredients in companion animals can result in self-limiting GI upset (eg, vomiting, diarrhea, anorexia, lethargy). However, toxicity is typically rare in pets.

Multivitamin preparations contain varying amounts of **iron**. Unless otherwise listed, iron should be assumed to be elemental iron. Various iron salts may contain 12%–48% elemental iron. Iron has direct caustic or irritant effects on the GI mucosa. It can also be a direct mitochondrial poison. Once the iron-carrying capacity of serum has been exceeded, free iron is deposited in the liver, where it damages mitochondria and leads to necrosis of periportal hepatocytes. Signs of iron toxicosis usually develop within 6 hr. Initial vomiting and diarrhea, with or without blood, may be followed by hypovolemic shock, depression, fever, acidosis, and liver failure 12–24 hr later, often with a period of apparent recovery in between. Oliguria and anuria secondary to shock-induced renal failure may also occur. Ingestion of elemental iron at >20 mg/kg generally warrants decontamination (emesis) and administration of GI protectants. Activated charcoal does not bind iron well. Additional treatment and monitoring is necessary for patients that have ingested elemental iron at >60 mg/kg. Milk of magnesia (magnesium hydroxide; 5–30 mL once or twice daily, per dog) can complex with iron to decrease its absorption from the GI tract. Serum iron levels and the total serum iron binding capacity should be checked at 3 hr and again at 8–10 hr after exposure. If serum iron is >300 mcg/dL along with clinical signs such as repeated vomiting and shock, or greater than the total iron binding capacity, chelation therapy may be needed. Deferoxamine (40 mg/kg, IM, every 4–8 hr) is a specific iron chelator and is most effective within 24 hr of ingestion, before iron has been distributed from blood to tissues. Other signs should be treated symptomatically.

Vitamin A toxicity after consumption of large amounts of fish oil or bear's liver has been well documented, but it is less likely to occur after acute ingestion of multivitamins. The amount of vitamin A needed to cause toxic effects is 10–1,000 times the dietary requirements for most species. The vitamin A requirement for cats is 10,000 IU/kg of diet fed, with levels up to 100,000 IU/kg of diet considered to be safe. For dogs, the requirement is 3,333 IU/kg of diet fed, with up to 333,300 IU/kg of diet considered to be safe. Signs associated with acute vitamin A toxicity include general malaise, anorexia,

nausea, peeling skin, weakness, tremors, convulsions, paralysis, and death.

Vitamin D is included in many calcium supplements to aid the absorption of the calcium. Most vitamins contain cholecalciferol (vitamin D₃). After consumption, cholecalciferol is converted into 25-hydroxycholecalciferol (calcifediol) in the liver, which is subsequently converted to the active metabolite 1,25-dihydroxycholecalciferol (calcitriol) in the kidneys. One IU of vitamin D₃ is equivalent to 0.025 mcg of cholecalciferol. Even though the oral LD₅₀ of cholecalciferol in dogs has been reported as 88 mg/kg, signs have been seen at dosages as low as 0.5 mg/kg. Vomiting, depression, polyuria and polydipsia, and hyperphosphatemia may be seen within 12 hr of a significant vitamin D exposure, followed by hypercalcemia and acute renal failure in 24–48 hr. In addition to renal failure, the kidneys, heart, and GI tract may show signs of necrosis and mineralization. Initial treatment should include decontamination and assessment of baseline calcium, phosphorus, BUN, and creatinine. Multiple doses of activated charcoal with a cathartic should be administered. If clinical signs of toxicosis and significant hypercalcemia/hyperphosphatemia develop, treatment consists of saline diuresis and the use of furosemide, corticosteroids, and phosphate binders. Specific agents such as (salmon) calcitonin or pamidronate may be needed for animals that remain hypercalcemic despite symptomatic treatment. Stabilization of serum calcium may require days of treatment because of the long half-life of calcifediol (16–30 days).

TOPICAL PREPARATIONS

Zinc Oxide

Zinc oxide ointments or creams are commonly used as topical skin protectants, astringents, and bactericidal agents. Most ointments contain 10%–40% zinc oxide. Acute ingestion of zinc oxide-containing products usually results in gastric irritation (vomiting) and diarrhea, without the intravascular hemolysis and liver and renal damage associated with ingestion of elemental zinc. Signs are usually seen within 2–4 hr of a significant exposure. Vomiting animals should be managed symptomatically and supportively. Some dogs show hypersensitivity-type reactions manifested by facial and ocular edema. Such cases can be treated with diphenhydramine or other antiallergic medications.

HERBAL SUPPLEMENTS

Ma Huang (Ephedrine) and Guarana (Caffeine)

Several herbal supplements, sold with the claim of providing weight loss and energy, contain guarana (*Paullinia cupana*), a natural source of caffeine, and ma huang (*Ephedra sinica*), a natural source of ephedrine. The amount of ma huang and guarana present in herbal products may vary considerably (labels should be read for amounts). In people, use of herbal supplements containing guarana and ma huang have been linked to acute hepatitis, nephrolithiasis, hypersensitivity myocarditis, and sudden death. In dogs, accidental ingestion of herbal supplements containing ma huang and guarana can have synergistic effects when ingested together and can lead to severe hyperactivity, tremors, seizures, vomiting, tachycardia, hyperthermia, and death within a few hours of exposure. The use of ephedra-containing supplements has been banned by the FDA. For treatment, see p 3027.

5-Hydroxytryptophan

Several OTC herbal supplements containing 5-hydroxytryptophan (5-HTP) or *Griffonia* seed extracts claim to treat depression, headaches, insomnia, and obesity. Orally, 5-HTP is rapidly absorbed and constitutively converted to serotonin (5-hydroxytryptamine). In cases of 5-HTP overdose, excessive concentrations of serotonin at target cells (GI, CNS, cardiovascular, and respiratory systems) can lead to a serotonin-like syndrome in dogs (eg, seizures, depression, tremors, ataxia, vomiting, diarrhea, hyperthermia, transient blindness, and death). Clinical signs can develop within 4 hr after ingestion and last up to 36 hr. Treatment consists of early decontamination, control of CNS signs (diazepam, barbiturates, phenothiazines such as acepromazine or chlorpromazine), thermoregulation (cool water bath, fans), fluid therapy, and administration of a serotonin antagonist such as cyproheptadine (1.1 mg/kg, PO or rectally for dogs, and 2–4 mg per cat, once or twice at an 8-hr interval).

Veterinarians also can prescribe certain human drugs for animals. Safety data for human prescription drugs in certain animal species may not be available—most are not approved for veterinary use by the FDA. A valid client-patient-veterinarian relationship must exist for veterinarians to recommend extra-label use of human prescription medications to their clients.

CARDIOVASCULAR MEDICATIONS

See also SYSTEMIC PHARMACOTHERAPEUTICS OF THE CARDIOVASCULAR SYSTEM, p 2525.

Angiotensin-converting Enzyme (ACE) Inhibitors

Several angiotensin-converting enzyme (ACE) inhibitors (eg, enalapril, captopril, lisinopril, benazepril) are used therapeutically to treat congestive heart failure in dogs and cats. The primary concern in cases of acute ACE inhibitor overdose is usually marked hypotension. If hypotension is severe, secondary renal damage may result. Onset occurs within a few hours of exposure, depending on the agent (extended-release formulations may have a delayed onset of action). Other clinical signs of overdose may include vomiting, poor mucous membrane color, weakness, and tachycardia or bradycardia. Activated charcoal is effective in binding the drug from the GI tract if administered within 1–2 hr of ingestion. Blood pressure should be monitored and IV fluids given at twice the maintenance rate if hypotension develops. Renal function should be monitored if severe or persistent hypotension develops.

Calcium Channel Blockers

Calcium channel blockers (eg, diltiazem, amlodipine, nifedipine, verapamil) inhibit movement of calcium from extracellular sites through cell membrane–based calcium channels. The most common signs seen with overdoses of calcium channel blockers are hypotension, bradycardia, GI upset, noncardiogenic pulmonary edema, and heart block. Reflex tachycardia may develop in response to the drop in blood pressure.

Management of an acute overdose includes correcting hypotension and rhythm disturbances. In general, emesis is induced within 2 hr of ingestion only if the animal is showing no clinical signs. Induction of emesis in animals with signs can increase vagal tone and worsen the bradycardia. Activated charcoal binds unabsorbed drug in the GI tract and is most

TOXICITIES FROM PRESCRIPTION DRUGS

Pets commonly ingest prescription medications from countertops, pill minders, mail-order packages, or other sources.

useful when administered within the first few hours after ingestion; if a sustained-release product was ingested, repeat doses of activated charcoal every 4–6 hr for a total of 2–4 doses can provide additional benefit. Specific therapies should be instituted based on blood pressure, heart rate, ECG, and blood chemistry profiles. IV fluids are recommended; calcium gluconate (10% solution at 0.5–1.5 mL/kg, slow IV) should be added while monitoring the ECG closely. Atropine (0.02–0.04 mg/kg) can be given for bradycardia; isoproterenol can be used if the ECG indicates atrioventricular block. For persistent hypotension not corrected by administration of IV fluids, synthetic colloids (Hetastarch), dopamine (1–20 mcg/kg/min), or dobutamine (2–20 mcg/kg/min) can be given via continuous IV infusion. A temporary cardiac pacemaker may be needed in cases of severe cardiac conduction disturbances unresponsive to medical therapy. Calcium channel blockers may interact with almost any other cardioactive medication, resulting in more profound bradycardia, hypotension, and depression of cardiac contractility. Because of the lipophilic nature of calcium channel blockers, using IV lipid emulsion solution (Intralipid™ 20% solution) may help sequester calcium channel blockers in overdose situations and prevent them from reaching their site of action. The recommended dose of 20% lipid emulsion solution in dogs is 1.5 mL/kg, IV, as an initial bolus followed by 0.25 mL/kg/min for 30–60 min. This dose can be repeated in 6 hr for a total of three treatments. Serum color and response should be monitored. If serum color is yellow, repeating the dose should be delayed until it becomes clear. If no response is seen after three doses, lipid emulsion should be discontinued. Hyperlipidemia, infection, intravascular hemolysis, lack of efficacy, and embolism are potential adverse effects associated with IV lipid emulsion therapy. The use of IV lipid emulsion for the treatment of some lipophilic drug overdoses is experimental and should be considered only if other conventional treatment options fail. Efficacy and safety of IV lipid emulsion has not been studied.

β Blockers

Drugs in this class (eg, propranolol, metoprolol, atenolol, timolol, esmolol) act by competitively inhibiting catecholamine binding to β-adrenergic receptor sites. The most common signs of overdose are

bradycardia and hypotension; respiratory depression, coma, seizures, hyperkalemia, and hypoglycemia may occur. It is also possible to precipitate congestive heart failure. Significant clinical signs may arise even at therapeutic (published) doses—no approved veterinary products are on the market.

Because of rapid absorption, emesis should only be induced in asymptomatic animals within 2 hr of ingestion. Administration of activated charcoal should be considered if either multiple tablets or capsules or sustained-release formulation tablets are ingested. Heart rate, blood pressure, and clinical condition should be monitored for several hours, because extended-release pills can lead to delayed onset of clinical signs. If clinical signs do develop, blood chemistries should also be measured. Hypotension should be treated with IV fluids; atropine can be used for bradycardia. Glucagon or isoproterenol can also be used if needed (*see above*). If hyperkalemia is confirmed, administration of insulin, followed by IV glucose, may drive the excess potassium back into the cells.

Phenylpropanolamine

Phenylpropanolamine (PPA) is a sympathomimetic amine used primarily for treating urinary incontinence in dogs and cats. PPA is believed to indirectly stimulate both α- and β-adrenergic receptors, causing the release of norepinephrine. It is rapidly absorbed orally and distributes to various tissues, including the CNS. PPA is mainly excreted through the kidneys as a parent drug. Overdose of PPA can result in CNS effects (restlessness, agitation, nervousness) and cardiovascular signs (hypertension or hypotension, tachycardia or bradycardia, premature ventricular contractions, cardiovascular collapse). Dogs can also show piloerection, hyperemia, vomiting, hyperthermia or hypothermia, and mydriasis. Treatment consists of early decontamination (emesis in asymptomatic animals within a couple of hours of ingestion, followed by administration of activated charcoal). CNS effects and mild hypertension can be managed with acepromazine (0.02 mg/kg, IV or IM, repeated as needed). A nitroprusside constant-rate infusion can be tried for hypertension not responsive to acepromazine. Lidocaine can be considered for treating premature ventricular contractions. IV fluids should be given to promote excretion. Other signs should be treated symptomatically.

Diuretics

Oral diuretic agents include thiazides (eg, chlorothiazide, hydrochlorothiazide), loop diuretics such as furosemide, and potassium-sparing agents such as spironolactone (an aldosterone antagonist) and triamterene. Osmotic diuretics, administered by injection, include mannitol and urea. The most common signs of diuretic overdose include vomiting, depression, polyuria and polydipsia, and electrolyte changes. Electrolytes, especially potassium, may shift subsequent to a large ingestion of a diuretic. Management should include monitoring hydration and electrolytes, with correction as needed.

TRANQUILIZERS, ANTIDEPRESSANTS, SLEEP AIDS, AND ANTICONVULSANTS

See also SYSTEMIC PHARMACOTHERAPEUTICS OF THE NERVOUS SYSTEM, p 2590.

Benzodiazepines

Benzodiazepines bind γ -aminobutyric acid (inhibitory neurotransmitter) receptors and are used for seizure control and as anxiolytics. Whereas diazepam is probably best known in the veterinary field, alprazolam, chlordiazepoxide, clonazepam, lorazepam, oxazepam, and triazolam are all commonly prescribed medications. In general, all are rapidly and fairly completely absorbed, lipophilic, and highly protein bound. Metabolism is mostly by glucuronidation, so cats may be more sensitive to adverse effects. Several have active metabolites (eg, diazepam, clorazepate) and consequently have much longer duration of signs.

The most common signs seen, at a wide range of dosages, are CNS depression, respiratory depression, ataxia, weakness, disorientation, nausea, and vomiting. Some animals, especially at high doses, may show CNS excitation instead of depression (paradoxical reaction), which may be followed by CNS depression. Other common signs are hypothermia, hypotension, tachycardia, muscle hypotonia, and meiosis. Some cats develop signs of acute, potentially fatal hepatic failure after repeated oral administration of diazepam for several days.

Emesis can be induced if ingestion is recent and no clinical signs are present. Gastric lavage, followed by administration of activated charcoal, can be performed if the ingested amount is very high. The animal should be kept warm and quiet and

closely monitored for responsiveness to stimuli and adequate breathing. IV fluids will help support blood pressure. If the affected animal is recumbent and severe respiratory depression has developed, the reversal agent flumazenil can be given at a dosage of 0.01 mg/kg, slow IV, in both cats and dogs. Flumazenil has a short half-life, so it may need to be repeated. Benzodiazepines should not be used to control CNS excitation, because a paradoxical reaction may occur. In such situations, low doses of acepromazine or barbiturates may be useful to control initial CNS excitation.

Antidepressants

Antidepressants fall into several classes. An overdose of almost any of them can result in development of serotonin syndrome (see below).

Selective Serotonin Reuptake

Inhibitors: Selective serotonin reuptake inhibitors (SSRIs) include sertraline, fluoxetine, paroxetine, and fluvoxamine. They block the activity of serotonin receptors at presynaptic membranes and have little effect on other neurotransmitters. In veterinary medicine, these SSRIs are sometimes used to control aggression, obsessive-compulsive disorder, separation anxiety, pruritus, and inappropriate elimination in dogs and cats. Overdosage of SSRIs in dogs and cats is manifested by vomiting, lethargy, mydriasis, ataxia, shaking, seizures, hyperactivity, tachycardia or bradycardia, and vocalization (see below).

Tricyclic Antidepressants: Tricyclic antidepressants (eg, amitriptyline, clomipramine, nortriptyline) are commonly used psychoactive agents. They are structurally similar to the phenothiazines, with similar anticholinergic, adrenergic, and α -blocking properties. After absorption, these agents are extensively bound to plasma proteins and also bind to tissue and cellular sites, including the mitochondria. Cyclic antidepressants block the amine pump and stop neuronal reuptake of norepinephrine, serotonin, and dopamine. These agents also appear to have a slight α -adrenergic blocking effect. Tricyclics may exert their major toxicity via a nonspecific membrane-stabilizing effect, similar to chlorpromazine and the β blockers. Tricyclics also have central and peripheral anticholinergic activity, along with antihistaminic effects. Clinical signs of toxicosis include CNS stimulation (agitation, confusion, pyrexia), cardiac arrhythmias,

hypertension, myoclonus, nystagmus, seizures, metabolic acidosis, urinary retention, dry mouth, mydriasis, and constipation. This may be followed by CNS depression (lethargy), ataxia, hypothermia, respiratory depression, cyanosis, hypotension, and coma.

Monoamine Oxidase Inhibitors: Monoamine oxidase inhibitors are antidepressants used mainly to treat atypical depression in people. In dogs, selegiline, a monoamine oxidase-B inhibitor, is used to treat Cushing disease and cognitive dysfunction (canine dementia). Selegiline is absorbed rapidly orally. Metabolites of selegiline include amphetamine and methamphetamine. Its half-life in dogs is ~1 hr.

Miscellaneous (Atypical) Antidepressants: These antidepressants have nonselective receptor-blocking effects and are used when SSRIs or tricyclic antidepressants have not been effective. Examples include bupropion, trazodone, and mirtazapine.

Treatment: Emesis should be induced in cases of recent exposure if the animal is asymptomatic. This can be followed by activated charcoal (even several hours after ingestion) plus a cathartic such as sorbitol or sodium sulfate (magnesium sulfate is contraindicated, because it can add to CNS depression). Diazepam can be given to control seizures. Serotonin syndrome signs should be managed as needed. Heart rate and rhythm should be monitored, and cardiac arrhythmias treated. Atropine should not be used to control bradycardia, because it can aggravate anticholinergic effects of tricyclic antidepressants.

Serotonin Syndrome: This group of clinical signs usually includes three of the following features: altered mental status, agitation, nervousness, myoclonus, hyperreflexia, tremors, diarrhea, incoordination, cardiovascular changes (heart rate and blood pressure), and fever. It often occurs because of repeated use or overdose or ingestion of substances that result in increased free levels of serotonin, such as antidepressants or profound stimulants (eg, amphetamines). Cyproheptadine is a serotonin antagonist often used for treatment. It is available only as a tablet but can be dissolved in a small amount of saline and administered per rectum at 1.1 mg/kg in dogs or 2 mg/dose in cats. If there is a good response to the initial dose, it can be repeated only if signs recur. Phenothiazines

such as acepromazine or chlorpromazine also have antiserotonergic effects and can be used to control hyperactivity. Benzodiazepines such as diazepam can be used to control CNS effects. β blockers such as propranolol (0.02–0.04 mg/kg, IV) can be used to control tachycardia. Other treatment measures may include induction of emesis in asymptomatic animals within 2 hr of exposure, followed by administration of activated charcoal and IV fluids.

Barbiturates

Both long-acting and short-acting barbiturates may be encountered. The long-acting group includes phenobarbital, mephobarbital, and primidone—all commonly used as anticonvulsants or sedatives. The short-acting (butabarbital, pentobarbital, secobarbital) and ultra short-acting (thiamylal and thiopental) barbiturates are used mainly for induction of anesthesia and seizure control. All are readily absorbed from the gut and have extensive liver metabolism; metabolites are primarily excreted via the kidneys. The onset of clinical signs varies from 15 min to several hours, and duration can be up to several days for the long-acting class. The most common signs are sedation, ataxia, respiratory depression, coma, loss of reflexes, hypotension, and hypothermia.

Management is aimed at life support while attempting to remove unmetabolized drug from the body. Emesis should be induced if the exposure is very recent and the animal is asymptomatic. Gastric lavage while protecting the airway can remove much of the drug still in the stomach. Activated charcoal readily adsorbs barbiturates; small doses repeated every 4–6 hr can further decrease the body burden, even if overdose has resulted from use of an injectable product. IV fluids can be given to support blood pressure. Respiratory effort and effectiveness needs to be closely monitored; treatment may require positive-pressure ventilation or oxygen. Doxapram (1–5 mg/kg, slow IV in dogs, and 5–10 mg/cat) may help to stimulate respiration. Support to maintain body temperature may be necessary. Comatose animals should be intubated with a cuffed endotracheal tube, because aspiration is a common complication. Depending on the dose, aggressive supportive treatment may be necessary for 1–3 days.

Sleep Aids

Zolpidem, zaleplon, and eszopiclone are drugs used as sleep aids and have a mechanism of action similar to that of the

benzodiazepines. These agents have a very rapid onset (usually <30 min) and a similarly short half-life. While the expected result from ingestion would be marked sedation, paradoxical excitement also occurs. Dosages as low as 0.22 mg/kg have resulted in sedation and ataxia, and dogs have developed tremors, vocalizing, and pacing at dosages as low as 0.6 mg/kg.

GI decontamination can be performed if the ingestion was recent and no signs are seen. For mild signs, keeping the pet quiet and in a safe place may suffice. If paradoxical excitement develops, symptomatic treatment should be given and will vary with the signs and their intensity. Hyperexcitation may be controlled with low doses of acepromazine or other phenothiazines. Use of diazepam may aggravate signs of CNS depression. Flumazenil (0.01 mg/kg, IV) can be used if clinical signs of toxicosis are severe.

Phenothiazine Tranquilizers

The most commonly used phenothiazines in veterinary medicine are acepromazine, chlorpromazine, and promazine. In domestic animals, they are used as tranquilizers, preanesthetic agents, antiemetics, and for treatment of CNS agitation after specific drug overdoses (amphetamines, cocaine). The most common signs of overdose are sedation, weakness, ataxia, collapse, behavioral changes, hypothermia, hypotension, tachycardia, and bradycardia.

Treatment consists of symptomatic and supportive care. Because of the rapid onset of CNS signs, emesis should only be attempted in a recent exposure and should be followed by administration of activated charcoal and a cathartic. Repeated doses of activated charcoal may be helpful, especially for large ingestions. Hypotension should be treated with IV fluids. Dopamine may be used if fluid administration does not correct hypotension. Body temperature, heart rate, and blood pressure should be monitored and treated symptomatically.

MUSCLE RELAXANTS

The most commonly encountered centrally acting muscle relaxants include baclofen, carisoprodol, methocarbamol, tizanidine, and cyclobenzaprine. Baclofen is rapidly absorbed orally. The onset of clinical signs of toxicosis may be <30 min to 2 hr after ingestion. The most common signs of toxicosis are vocalization, salivation, vomiting, ataxia, weakness, tremors,

shaking, coma, seizures, bradycardia, hypothermia, and blood pressure abnormalities. Cyclobenzaprine, often used in management of acute muscle spasms, is almost completely absorbed after an oral dose, with peak plasma levels in 3–8 hr. It has extensive liver metabolism and undergoes enterohepatic recirculation. The most common signs seen in dogs and cats include depression and ataxia.

Treatment of muscle relaxant overdose consists of symptomatic and supportive care. Vomiting should be induced if the exposure is recent and no clinical signs are present, followed by administration of activated charcoal. Respiratory support (ie, ventilator) should be provided if needed. Recumbent or comatose animals should be monitored for hypothermia and aspiration. Seizures can be controlled with diazepam. Cyproheptadine (1.1 mg/kg, PO, once or twice every 8 hr) seems to work well for vocalization in dogs. IV fluids should be given as needed. Treatment with IV lipid emulsion solution may be beneficial (*see p 3032*).

TOPICAL AGENTS

Pets ingest many topical preparations, often resulting in only mild gastroenteritis. For example, ingestion of most corticosteroid-containing creams or ointments usually results in only mild to moderate stomach upset, polydipsia, and polyphagia. However, ingestion of certain topical agents in pet animals, such as 5-fluorouracil and calcipotriene, can be fatal even at low doses.

5-Fluorouracil

5-Fluorouracil (5-FU) is available as an ointment (1% or 5%) or topical solution (1%, 2%, or 5%). It is used in the treatment of skin cancers and solar keratoses in people. Most exposures result from accidental ingestion, although occasionally 5-FU is used extra-label in pets. Ingestion in dogs and cats leads to the onset of signs within a few hours. In dogs, signs have been seen at dosages as low as 8.6 mg/kg, with the minimum lethal dose reported as 20 mg/kg. Initial signs include severe vomiting, which may progress to bloody vomiting and diarrhea. Signs often progress to severe tremors, ataxia, and seizures. In cats and dogs, 5-FU may be converted to fluorocitrate and interfere with the Krebs's cycle, which may be one cause of seizures and ataxia. Generally, 5-FU destroys rapidly dividing cells, affecting the GI tract, liver,

kidneys, CNS, and bone marrow. The mortality rate among dogs ingesting 5-FU is high.

All 5-FU exposures in pets should be treated aggressively. Treatment consists primarily of symptomatic and supportive care. Emesis should be induced, and the animal given activated charcoal and a cathartic if it is asymptomatic and the ingestion has occurred within 1 hr. Symptomatic animals (eg, vomiting or seizing) should be stabilized first. The GI tract should be protected with sucralate (1 g in large dogs, 0.5 g in small dogs, PO, tid) and inhibitors of gastric acid secretion such as cimetidine. Diazepam may be used initially to control seizures and tremors, but in severe cases it is usually not effective, and other anticonvulsants such as pentobarbital (3–15 mg/kg, IV slowly to effect) or phenobarbital (3–30 mg/kg, slowly IV to effect) can be used. Constant-rate infusion using diazepam or barbiturates has successfully controlled severe seizures. If this also fails to control CNS signs, gas anesthetics (eg, isoflurane) and propofol (4–6 mg/kg, IV, or as a continuous drip at 0.6 mg/kg/min) can be tried. IV fluids should be given, and body temperature monitored. Monitoring electrolytes, serum chemistries (liver-specific enzymes and renal function), and CBC is usually required for ~2 wk. Surviving dogs may show evidence of bone marrow suppression later. For severe neutropenia in dogs, administration of filgrastim or granulocyte colony-stimulating factor at 4–6 mcg/kg, SC, may be useful.

Calcipotriene

Calcipotriene, used to treat psoriasis in people, is available as an ointment or cream (0.005% or 50 mcg/g). Calcipotriene is a novel structural analogue of calcitriol (1,25-dihydroxycholecalciferol), the most active metabolite of cholecalciferol (vitamin D₃). Accidental ingestion of 40–60 mcg/kg of calcipotriene in dogs has been associated with life-threatening hypercalcemia. Clinical signs usually occur within 24–72 hr of ingestion and include anorexia, vomiting, diarrhea, polyuria and polydipsia, depression, and weakness. Serum calcium is usually increased within 12–24 hr and may remain above normal for weeks. This is usually accompanied by an increase in serum phosphorus concentration and calcium phosphorus product and soft-tissue mineralization. Acute renal failure as evidenced by increased BUN and creatinine levels, coma, and death occur in severe or untreated cases.

Treatment of calcipotriene toxicosis involves standard decontamination (emesis induction, administration of activated charcoal and a cathartic) and reduction of serum calcium concentrations by saline diuresis, furosemide, and corticosteroids, with or without salmon calcitonin treatment (*see* p 568). Concurrent use of pamidronate (1.3–2 mg/kg diluted in saline and given IV over 2 hr) in dogs may be a useful adjunctive therapy. Calcipotriene toxicosis cases usually require monitoring of serum calcium, phosphorus, BUN, and creatinine for several days or even weeks. Signs of renal failure are managed with ongoing supportive fluids.

PRESCRIPTION NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

For a general discussion of commonly seen adverse effects and treatment of NSAID toxicosis, *see* p 3027.

Etodolac

Etodolac is an indole acetic acid-derivative NSAID labeled for use in dogs to treat pain and inflammation associated with osteoarthritis. It is rapidly absorbed orally, with peak serum concentrations seen 2 hr after dosing. It is primarily eliminated through the bile. The elimination half-life is 8–12 hr. Etodolac appears to be well tolerated by dogs when used at the labeled dosage (10–15 mg/kg/day, PO) for 1 yr. With multiple doses, clinical signs of toxicity such as GI ulcers, vomiting, diarrhea, and weight loss can be seen at 40 mg/kg. Six of 8 dogs died or became moribund because of GI ulceration at 80 mg/kg.

Meloxicam

Meloxicam is an enolic acid-derivative NSAID approved for use in dogs and cats for controlling pain and inflammation. Meloxicam is available as a solution for injection (5 mg/mL) and as an oral suspension. In cats, it has been approved for use as a single SC injection at 0.3 mg/kg. In dogs, the recommended initial dosage is 0.2 mg/kg, followed by 0.1 mg/kg, PO. Meloxicam has a good margin of safety in dogs. Oral administration at 0.1 mg/kg for 26 weeks was well tolerated in dogs. Some dogs at 0.3 or 0.5 mg/kg, PO, for 42 days have shown clinical signs consistent with NSAID toxicity (vomiting, diarrhea, renal effects). In cats, the margin of safety appears to be narrow; extra-label dosing at 0.1–0.2 mg/kg, PO, for a few days has caused adverse effects.

Deracoxib

Deracoxib is a coxib COX-2 inhibitor (in vitro) used to treat osteoarthritis in dogs. It is not approved for use in cats. The recommended dosage is 1–2 mg/kg/day or 3–4 mg/kg/day as needed for postoperative pain, not to exceed 7 days of therapy. Oral bioavailability in dogs is > 90%; the time to peak serum concentration is ~2 hr. In a 14-day study of dogs that received 10 mg/kg, no clinically observable adverse effects were seen. Dogs that received 25 mg/kg/day, 50 mg/kg/day, or 100 mg/kg/day for 10–11 days showed vomiting and melena; no hepatic or renal lesions were seen in these dogs. Dogs ingesting >100 mg/kg should be aggressively decontaminated and treated with IV fluids to prevent renal damage.

Piroxicam

Piroxicam is an oxicam derivative. It is not approved in dogs and cats but has been used at 0.3 mg/kg, PO, every other day. Piroxicam in dogs and people has a long half-life (40 hr and 50 hr, respectively) likely due to extensive enterohepatic recirculation. The LD₅₀ of piroxicam in dogs is >700 mg/kg. Adverse GI effects were seen in 18% of dogs given piroxicam at 0.3 mg/kg/day, PO, for several months.

Diclofenac

Diclofenac is a phenylacetic acid derivative structurally related to meclofenamate sodium and mefenamic acid. After a single injection of diclofenac sodium at 1 mg/kg in dogs, 35%–40% is excreted in the urine. The reported oral LD₅₀ of diclofenac sodium in dogs is 500 mg/kg.

Indomethacin

Indomethacin is an indole acetic acid derivative available as the base and as the sodium trihydrate salt. The drug is structurally and pharmacologically related to another NSAID, sulindac. The reported oral LD₅₀ of indomethacin in rats is 12 mg/kg. Administration of indomethacin to dogs at 2 mg/kg for 30 days resulted in GI ulcers in 60% of dogs and perforation in 20%.

Etodolac

Etodolac, an indole acetic acid derivative, is used for pain relief, osteoarthritis, and rheumatoid arthritis in people. It is approved in the USA for use in dogs (>12 mo old) to manage pain and inflammation associated with osteoarthritis. The suggested dosage in dogs is 10–15 mg/kg.

Etodolac is well absorbed orally in dogs, with peak plasma concentration seen in 2 hr. It is primarily excreted through bile, and the half-life in dogs is 8–12 hr. In dogs, etodolac at 40 mg/kg/day was associated with GI ulcers, weight loss, emesis, and local occult blood loss. Dosages of 80 mg/kg/day caused 6 of 8 dogs to die or become moribund because of GI ulceration.

Nabumetone

Nabumetone differs from other NSAIDs in that it is neutral as opposed to acidic. The risk of GI ulcers from nabumetone is considered less than that of other NSAIDs. Nabumetone is primarily excreted in the urine in most species. However, in dogs, when nabumetone was administered at 20 mg/kg, only 27% of the dose was found in the urine. The reported oral LD₅₀ of nabumetone in rats is >2 g/kg. At a dosage of >300 mg/kg, the lower GI tract and the kidneys were affected in rats, mice, rabbits, and rhesus monkeys.

TOXICITIES FROM ILLICIT AND ABUSED DRUGS

Exposures to illicit or abused drugs in pet animals can be accidental, intentional, or malicious. Occasionally, drug-sniffing dogs also ingest these substances. Because of the illegal nature of illicit or abused drugs, owners may provide inaccurate, incomplete, or misleading exposure histories. Illicit drugs are often adulterated with other pharmacologically active substances, making the diagnosis even more difficult.

In suspected cases of exposure to illicit or abused drugs, an attempt should be made to gather information about the animal's environment; amount of exposure; and time of onset of clinical signs and their type, severity, and duration. These questions will help include or exclude possible exposure to an illicit or abused drug. Illicit and abused drugs are often known by street names that vary from area to area. A call to a local police station, or animal or human poison control center, may help identify the illicit substance if its street name is known. Most human hospitals, emergency clinics, and some veterinary diagnostic laboratories have illicit drug screens available and can check for the presence of illicit drugs or their metabolites in different body fluids. The presence of a parent drug or its metabolites in blood or urine may help confirm exposure in suspect cases. The laboratories should be contacted for information on the types of samples needed

and time required to complete the screens or tests.

Commonly available over-the-counter drug test kits may help exclude a suspected case of illicit drug toxicosis. They are designed to detect drug metabolites in the urine and can detect most commonly available illicit or recreational drugs such as amphetamines, cocaine, marijuana, opiates, and barbiturates. The sensitivities and specificities of these test kits may vary. The kits are inexpensive, efficient, and easy to use, but the instructions provided with each kit should be followed carefully for best results.

Amphetamines and Related Drugs

Amphetamines and their derivatives are CNS and cardiovascular system stimulants commonly used in people for suppression of appetite, narcolepsy, attention deficit disorder, parkinsonism, and some behavior disorders. Some commonly encountered amphetamines or related drugs are benzphetamine, dextroamphetamine, lisdexanfetamine, pemoline, methylphenidate, phentermine, diethylpropion, phendimetrazine, methamphetamine, and phenmetrazine. Amphetamines sold on the street have common names such as speed, bennies, or uppers. Commonly used adulterants are caffeine, ephedrine, or phenylpropanolamine.

Pharmacokinetics and Toxicity:

Amphetamines are rapidly absorbed in the GI tract, reaching peak plasma concentrations in 1–2 hr. Sustained-release formulations have a delayed absorption and relatively longer half-life. The plasma half-life of amphetamines depends on the urinary pH. With an alkaline pH, the half-life is 15–30 hr; with an acidic pH, the half-life is 8–10 hr. The acute oral LD₅₀ of amphetamine in rats and mice is 10–30 mg/kg. In people, deaths have been reported after ingestion of methamphetamine at 1.3 mg/kg.

Pathogenesis: Amphetamine stimulates the release of norepinephrine, affecting both α - and β -adrenergic receptor sites. Amphetamine also stimulates catecholamine release centrally in the cerebral cortex, medullary respiratory center, and reticular activating system. It increases the amount of catecholamine at nerve endings by increasing release and inhibiting reuptake and metabolism. The neurotransmitters affected in the CNS are norepinephrine, dopamine, and serotonin.

Clinical Findings and Diagnosis:

Clinical signs of amphetamine and cocaine toxicosis are similar and difficult to differentiate clinically. The only difference may be the longer duration of clinical signs of amphetamine toxicosis because the half-life of amphetamine is longer than that of cocaine. The most commonly reported signs are hyperactivity, aggression, hyperthermia, tremors, ataxia, tachycardia, hypertension, mydriasis, circling, head bobbing, and death.

Diagnosis is as for cocaine (*see below*) and relies mostly on owner knowledge of exposure. Most amphetamines and related drugs or their metabolites are detectable in the stomach contents and urine. They are difficult to detect in plasma unless large amounts have been ingested.

Treatment: Phenothiazines are preferred to control CNS signs in amphetamine toxicosis (*see below* for cocaine toxicosis). Other anticonvulsants, such as diazepam, barbiturates, or isoflurane, may be used if needed. Acidifying the urine with ammonium chloride (25–50 mg/kg/day, PO, qid) or ascorbic acid (20–30 mg/kg, PO, SC, IM, or IV) may enhance amphetamine elimination in the urine. However, this should be done only if acid-base status can be monitored. Cyproheptadine (1.1 mg/kg, PO or per rectum) may also be given once or twice (6–8 hr apart) for serotonin syndrome (disorientation, muscle stiffness, agitation). Heart rate and rhythm (*see* p 3040 for using β blockers to treat tachycardia), body temperature, and electrolytes should be monitored and treated as needed.

Cocaine

Cocaine (benzoylmethylecgonine) alkaloid is obtained from the leaves of the coca plant, *Erythroxylon coca* and *E monogynum*. Some common street names for cocaine are coke, gold dust, stardust, snow, C, white girl, white lady, baseball, and speedball (cocaine and heroin). Cocaine alkaloid from coca leaves is processed into cocaine hydrochloride salt, then reprocessed to form cocaine alkaloid or free base (a process called free-basing or base balling), which is colorless, odorless, transparent, and more heat stable. Free-base cocaine is also called crack, rock, or flake. Cocaine is cut (diluted) several times before it reaches the user. Xanthine alkaloids, local anesthetics, and decongestants are some of the most common adulterants.

Cocaine is a schedule II drug approved for human use. Its medical uses are restricted to topical administration as a local anesthetic on mucous membranes of the oral, laryngeal, and nasal cavities. However, it is mostly used as a recreational drug.

Pharmacokinetics and Toxicity:

Cocaine is absorbed from most routes. Orally, it is better absorbed in an alkaline medium (ie, intestine). In people, ~20% of an oral dose is absorbed. The reported plasma half-life is 0.9–2.8 hr. Cocaine is extensively metabolized by liver and plasma cholinesterases to several inactive metabolites that are primarily excreted in the urine. The acute LD₅₀ of cocaine hydrochloride administered IV in dogs is 13 mg/kg; the LD₁₀₀ is 12 mg/kg in dogs and 15 mg/kg in cats. The oral LD₅₀ in dogs is believed to be 2–4 times more than the IV dose.

Pathogenesis: Cocaine acts on the sympathetic division of the autonomic nervous system. It blocks the reuptake of dopamine and norepinephrine in the CNS, leading to feelings of euphoria, restlessness, and increased motor activity. Cocaine can also decrease concentrations of serotonin or its metabolites. Topical use of cocaine causes vasoconstriction of small vessels. Hyperthermia in cocaine toxicosis may develop either due to increased heat production from muscular activity or due to decreased heat loss from vasoconstriction.

Clinical Findings and Diagnosis: CNS excitation, hyperactivity, shaking, ataxia, panting, agitation, mydriasis, nervousness, seizures, tachycardia, hypertension, acidosis, or hyperthermia characterize cocaine toxicosis. CNS depression and coma may follow CNS excitation. Death may be due to hyperthermia, cardiac arrest, or respiratory arrest. Some nonspecific chemistry changes may include hyperglycemia and increased CK and liver-specific enzymes.

Diagnosis is based on a history of exposure and the presence of characteristic clinical signs. Identification of cocaine in plasma, stomach contents, or urine can confirm exposure. Differential diagnoses include amphetamines, pseudoephedrine, ephedrine, caffeine, chocolate, metaldehyde, strychnine, tremorgenic mycotoxins, lead, nicotine, permethrin (cats) and other pesticides, and encephalitis.

Treatment: The objectives of treatment are GI decontamination, stabilization of CNS and cardiovascular effects, thermoregulation, and supportive care. Animals with

clinical signs should be stabilized first before attempting decontamination. Emesis can be induced in a recent exposure if the animal is asymptomatic and has the ability to guard its airway via a gag reflex. This should be followed by administration of activated charcoal with a cathartic. If the animal's condition contraindicates induction of emesis (eg, presence of CNS signs or extreme tachycardia), a gastric lavage with a cuffed endotracheal tube to reduce the risk of aspiration should be performed. A dose of activated charcoal with a cathartic should be left in the stomach after the lavage.

Controlling the CNS signs may require use of more than one anticonvulsant. Clinical signs of CNS excitation can be controlled with diazepam; however, the effects of diazepam are short-lived, and repeated administration may be needed. Phenothiazine tranquilizers such as acepromazine (0.05–1 mg/kg, IV, IM, or SC, repeated as needed) or chlorpromazine (0.5–1 mg/kg, IV or IM) also usually work well to control the CNS effects. However, phenothiazines should be used cautiously, because they may lower the seizure threshold. If phenothiazines are ineffective, phenobarbital at 3–4 mg/kg, IV, or pentobarbital, IV to effect, could be used. If CNS signs are uncontrolled by the preceding measures, a gas anesthetic such as isoflurane may be useful.

Blood pressure, heart rate and rhythm, ECG, and body temperature should be monitored frequently and treated as needed. Propranolol at 0.02–0.06 mg/kg, IV, tid-qid, or other β -blocking agents such as esmolol (0.2–0.5 mg/kg, slow IV over 1 min, or 25–200 mcg/kg/min as a constant-rate infusion) can be used to control tachycardia. After CNS and cardiovascular effects have been stabilized, IV fluids should be administered, and electrolyte changes and acid-base status monitored and corrected as needed. Treatment and monitoring should continue until all clinical signs have resolved.

Ecstasy (MDMA or 3,4-Methylenedioxymethamphetamine)

Ecstasy is a semisynthetic psychoactive designer drug (developed by street chemists with minor structural changes in parent compounds) with hallucinogenic and amphetamine-like properties. Street names include Adam, XTC, E, Roll, X, or Love Drug. A typical dose may be 75–150 mg. MDMA is believed to cause excessive release of serotonin. It also binds to serotonin transporter (a protein), which is responsible for removing serotonin from the synapse. The overall effect is increased serotonin and

serotonergic effects. MDMA also affects dopamine and norepinephrine. Studies in rodents indicate that use of MDMA can lead to permanent serotonergic neuronal injury.

In pets, MDMA toxicosis is not common. It is usually acute and occurs from accidental ingestion (powder, pills, or capsules). Clinical signs develop within 30 min to 2 hr after ingestion and may consist of sympathomimetic effects (CNS excitation, agitation, hyperactivity, pacing, hyperthermia, tachycardia, hypertension, seizures [just like amphetamines]), sedation, or signs thought to be related to hallucination (vocalization, disorientation, muscle rigidity). The half-life in people is 7.6–8.7 hr. Treatment is similar to that for amphetamine toxicosis (see p 3039). For serotonergic effects (agitation, muscle rigidity, nervousness), antiserotonergic drugs such as cyproheptadine can be tried (1.1 mg/kg, PO, repeated once in 6–8 hr).

Marijuana

Marijuana refers to a mixture of cut, dried, and ground flowers, leaves, and stems of the leafy green hemp plant *Cannabis sativa*. Several cannabinoids are present in the plant resin, but delta-9-tetrahydrocannabinol (THC) is considered the most active and main psychoactive agent. The concentration of THC in marijuana varies between 1%–8%. Hashish is the resin extracted from the top of the flowering plant and is higher in THC concentration than marijuana. Street names for marijuana include pot, Mary Jane, hashish, weed, grass, THC, ganja, bhang, and charas. Pure THC is available by prescription under the generic name dronabinol. A synthetic cannabinoid, nabilone, is also available. Marijuana or hashish sold on the streets may be contaminated with phencyclidine, LSD, or other drugs.

Marijuana is a schedule I controlled substance mostly used by people as a recreational drug. It is also used as an antiemetic for chemotherapy patients and to decrease intraocular pressure in glaucoma patients. Some clinicians advocate the use of dronabinol as an appetite stimulant, but the dysphoric effects of this drug outweigh any benefit of appetite stimulation.

Synthetic marijuana is a designer drug in which different herbs or incense or other leafy materials are sprayed with laboratory-synthesized chemicals. The use of synthetic marijuana produces psychoactive effects similar to those of THC. It is often claimed to be natural, safe, and legal. Spice, K-2, skunk, and moon rocks are some of the

common street names. Clinical signs of toxicosis from ingestion of synthetic marijuana in dogs can be more severe and last longer than those of THC.

Pharmacokinetics and Toxicity: The most common route of exposure is oral. After ingestion, THC goes through a substantial first-pass effect. It is metabolized by liver microsomal hydroxylation and nonmicrosomal oxidation. In dogs, clinical signs begin within 30–90 min and can last up to 72 hr. THC is highly lipophilic and readily distributes to the brain and other fatty tissues after absorption. The oral LD₅₀ of pure THC is 666 mg/kg in rats and 482 mg/kg in mice. However, clinical effects of marijuana are seen at much lower doses than this.

Pathogenesis: THC is believed to act on a unique receptor in the brain that is selective for cannabinoids and is responsible for the CNS effects. Cannabinoids can enhance the formation of norepinephrine, dopamine, and serotonin. They can also stimulate release of dopamine and enhance γ -aminobutyric acid turnover.

Clinical Findings and Diagnosis: The most common signs of marijuana toxicosis are depression, ataxia, bradycardia, hypothermia, vocalization, hypersalivation, vomiting, diarrhea, urinary incontinence, seizures, and coma.

Diagnosis is based on a history of exposure and typical clinical signs. THC is difficult to detect in body fluids because of the low levels found in the plasma. Urine testing at human hospitals or using an over-the-counter marijuana drug test kit in the early course of exposure may help confirm the diagnosis. Marijuana toxicosis can be confused with ethylene glycol (antifreeze, see p 3046) or ivermectin toxicosis; hypoglycemia; benzodiazepine, barbiturate, or opioid overdose; intervertebral disc problems; or head trauma.

Treatment: Treatment consists of supportive care. If the exposure is recent and there are no contraindications, emesis should be induced and activated charcoal administered. Comatose animals should be monitored for aspiration pneumonia, given IV fluids, treated for hypothermia, and rotated frequently to prevent dependent edema or decubital ulceration. Diazepam can be given for sedation or to control seizures. Treatment and monitoring should continue until all clinical signs have resolved (up to 72 hr in dogs). For cases of

synthetic marijuana toxicosis, in addition to the preceding treatment options, use of IV lipid emulsion solution may be considered.

Opiates

The term opiate initially referred to all naturally occurring alkaloids obtained from the sap of the opium poppy (*Papaver somniferum*). Opium sap contains morphine, codeine, and several other alkaloids. Currently, opioid refers to all drugs, natural or synthetic, that have morphine-like actions or actions mediated through opioid receptors. Structurally, opioids can be divided into five classes. Some of the common agents within each class are 1) phenanthrenes—morphine, heroin, hydromorphone, oxycodone, hydrocodone, codeine, and oxycodone; 2) morphinan—butorphanol; 3) diphenylheptanes—methadone and propoxyphene; 4) phenylpiperidines—meperidine, diphenoxylate, fentanyl, loperamide, and prochlorperazine; and 5) benzomorphans—pentazocine and buprenorphine. Some of the widely used opioids in veterinary medicine include tramadol, buprenorphine, fentanyl, loperamide (antidiarrheal), and hydromorphone. The use of meperidine is no longer common.

Opioids are used primarily for analgesia. In addition, they are used as cough suppressants and to treat diarrhea. Occasionally, opioids are used for sedation before surgery and as a supplement to anesthesia.

Pharmacokinetics and Toxicity: Opioids are generally well absorbed after oral, rectal, or parenteral administration. Some more lipophilic opioids are also absorbed through nasal, buccal, respiratory (heroin, fentanyl, buprenorphine), or transdermal (fentanyl) routes. For some opioids, there is variable reduction in bioavailability because of a first-pass effect when given orally. Opioids generally undergo hepatic metabolism with some form of conjugation, hydrolysis, oxidation, dealkylation, or glucuronidation. Because cats are deficient in glucuronidase, the half-life of some opioids in cats may be prolonged. After absorption, opioids are rapidly cleared from blood and stored in kidney, liver, brain, lung, spleen, skeletal muscle, and placental tissue. Most of the opioid metabolites are excreted through the kidneys.

Toxicity of opioids in animals is highly variable. In dogs, morphine administered at 100–200 mg/kg, SC or IV, is considered lethal. The estimated lethal dose of codeine

in human adults is 7–14 mg/kg; in infants, 2.5 mg of hydrocodone has been lethal.

Pathogenesis: The effects of opioids are due to their interaction with opiate receptors (μ , κ , δ , σ , and ϵ) found in the limbic system, spinal cord, thalamus, hypothalamus, striatum, and midbrain. Opioids may be agonists, mixed agonist-antagonists, or antagonists at these receptors. Agonists bind and activate a receptor, whereas antagonists bind without causing activation.

Clinical Findings: The primary effects of opioids are on the CNS, respiratory, cardiovascular, and GI systems. Commonly reported clinical signs of toxicosis include CNS depression, drowsiness, ataxia, vomiting, seizures, miosis, coma, respiratory depression, hypotension, constipation/defecation, and death. Some animals—especially cats, horses, cattle, and swine—can show CNS excitation instead of CNS depression.

Diagnosis: Diagnosis of opioid toxicosis is based on history of exposure and the types of clinical signs (CNS and respiratory depression) present. Plasma opioid levels are usually not clinically useful. Urine may be used to determine exposure to opioids using some of the over-the-counter illicit drug kits (manufacturer's instructions should be followed). Opioid toxicosis should be differentiated from ethylene glycol, ivermectin, benzodiazepine, barbiturate, and marijuana toxicosis, as well as hypoglycemia-inducing conditions.

Treatment: Clinical signs can be reversed with the opiate antagonist naloxone. The dosages in different species are dog and cat, 0.04–0.16 mg/kg, IV, IM, or SC; rabbit and rodent, 0.01–0.1 mg/kg, SC or IP; horse, 0.01–0.02 mg/kg, IV. Administration of naloxone should be repeated as needed (hourly), because its duration of action may be shorter than that of the opioid toxicity being treated. Animals should be closely monitored for respiratory depression and ventilatory support provided if needed. Other signs should be treated symptomatically. Dysphoric reactions (vocalization, agitation, restlessness, and excitation) can be treated with diazepam or other benzodiazepines. For serotonin-like syndrome (disorientation, muscle rigidity, agitation) induced by some opioids, cyproheptadine (1.1 mg/kg, PO or per rectum) once or twice (6–8 hr apart) can be tried.

NONPROTEIN NITROGEN POISONING

(Ammonia toxicosis)

Poisoning by ingestion of excess urea or other sources of nonprotein nitrogen (NPN) is usually acute, rapidly progressive, and highly fatal. NPN is any source of nitrogen not present in a polypeptide (precipitable protein) form. Sources of NPN have different toxicities in various species, but mature ruminants are affected most commonly. After ingestion, NPN undergoes hydrolysis and releases excess ammonia (NH_3) into the GI tract, which is absorbed and leads to hyperammonemia.

Etiology: Ruminants use NPN by converting it via the ruminal microflora to ammonia, which is then combined with carbohydrate-derived keto acids to form amino acids. The most common sources of NPN in feeds are urea, urea phosphate, ammonia (anhydrous), and salts such as monoammonium and diammonium phosphate. Because feed-grade urea is unstable, it is formulated (usually pelleted) to prevent degradation to NH_3 . Biuret, a less toxic source of NPN, is being used less frequently than in the past. Natural protein sources such as rice hulls, beet or citrus pulp, cottonseed meal, and straw or other low-quality forages may be treated with anhydrous ammonia to increase available nitrogen in supplemented livestock diets. Fermentation byproducts from alcohol (ethanol) manufacture are a source of NPN that comes from incomplete proteins, and these products are commonly used in liquid or feed supplements. Most sources of NPN are provided to ruminants by direct addition of dry supplement to a complete mixed or blended diet, by free-choice access to NPN-containing range blocks or cubes, or by lick tank systems combined with molasses as a supplement. Ammonia or NPN poisoning is a common sequela of abrupt change to urea or other NPN in the diet when only natural protein was previously fed; animals have to be gradually acclimated to NPN so that rumen microflora can increase in numbers to use the NH_3 produced. Also, farm animals sometimes drink liquid fertilizers or ingest dry granular fertilizers that contain ammonium salts or urea.

Ruminants are most sensitive, because urease is normally present in the functional rumen after 50 days of age. Dietary exposure of unacclimated ruminants to 0.3–0.5 g of

urea/kg body wt may cause adverse effects; dosages of 1–1.5 g/kg are usually lethal. Urease activity in the equine cecum is ~25% that of the rumen, and horses may receive NPN as a feed additive; however, horses are more sensitive to urea than other monogastrics, and dosages ≥ 4 g/kg can be lethal. Ammonium salts at 0.3–0.5 g/kg may be toxic in all species and ages of farm animals; dosages ≥ 1.5 g/kg usually are fatal. Pigs and neonatal calves are generally unaffected by ingestion of urea except for a transient diuresis. Wild birds (silver gulls) reportedly have been poisoned after consuming water contaminated with urea fertilizer spillage.

Livestock may require days or weeks for total adaptation before rumen microflora can utilize the gradually increasing amounts of urea or other NPN in the diets; however, adaptation is lost relatively quickly (1–3 days) once NPN is removed from the diet.

Diets low in energy and high in fiber are more commonly associated with NPN toxicosis, even in acclimated animals. Highly palatable supplements (such as liquid molasses or large protein blocks crumbled by precipitation), range cubes, or improperly maintained lick tanks may lead to consumption of lethal amounts of NPN.

A related CNS disorder in cattle fed ammoniated high-quality hay, silage, molasses, and protein blocks is thought to be caused by formation of 4-methylimidazole (4-MI) through the action of NH_3 on soluble carbohydrates (reducing sugars) in these feedstuffs. Cattle fed dietary components containing 4-MI develop a syndrome known as the “bovine bonkers syndrome,” named for the wildly aberrant behavior exhibited. Signs relate to CNS effects, with stampeding, ear twitching, trembling, champing, salivating, and convulsions. Because nursing calves are affected, the toxic principle apparently is excreted in milk. Ammoniated low-quality forages do not have sufficient concentrations of reducing sugars to form 4-MI, and thus serve as a relatively safe nitrogen source for acclimated animals.

Another related disorder involves accidental excessive exposure of ruminants (cattle and sheep) to raw soybeans. Soybeans have high concentrations of both carbohydrates and proteins, as well as urease. Overconsumption can cause acute carbohydrate fermentation and excessive

ammonia release, resulting in ammonia toxicosis and lactic acidosis. Affected animals have engorged rumens with a gray, amorphous mass inside.

Clinical Findings: The period from urea ingestion to onset of clinical signs is 20–60 min in cattle, 30–90 min in sheep, and longer in horses. Early signs include muscle tremors (especially of face and ears), exophthalmia, abdominal pain, frothy salivation, polyuria, and bruxism. Tremors progress to incoordination and weakness. Pulmonary edema leads to marked salivation, dyspnea, and gasping.

Horses may exhibit head pressing; cattle are often agitated, hyperirritable, aggressive, and belligerent as toxicosis progresses; sheep usually appear depressed. An early sign in cattle is ruminal atony; as toxicosis progresses, ruminal tympany is usually evident, and violent struggling and bellowing, a marked jugular pulse, severe twitching, tetanic spasms, and convulsions may be seen. Affected cattle with belligerent aberrant behavior may have produced some 4-MI in vivo through reaction of excessive NH_3 , released from NPN, with carbohydrates and reducing sugars in the rumen. The PCV and serum concentrations of NH_3 , glucose, lactate, potassium, phosphorus, AST, ALT, and BUN usually are significantly increased.

As death nears, animals become cyanotic, dyspneic, anuric, and hyperthermic, and blood pH decreases from 7.4 to 7.0. Regurgitation may occur, especially in sheep. Death related to excess NPN usually occurs within 2 hr in cattle, 4 hr in sheep, and 3–12 hr in horses. Survivors recover in 12–24 hr with no sequelae.

Carcasses of animals dying of NPN poisoning appear to bloat and decompose rapidly, with no specific characteristic lesions. Gross brain lesions are not usually reported in NPN-induced ammonia toxicosis, but histopathologic lesions may include neuronal degeneration, spongy degeneration of the neuropil, and congestion and hemorrhage in the pia mater. Frequently, pulmonary edema, congestion, and petechial hemorrhages may be seen. Mild bronchitis and catarrhal gastroenteritis are often reported. Regurgitated and inhaled rumen contents are commonly found in the trachea and bronchi, especially in sheep. The odor of NH_3 may or may not be apparent in ingesta from a freshly opened rumen or cecum. A ruminal or cecal pH ≥ 7.5 from a recently dead animal is highly suggestive of NPN poisoning. The ruminal pH remains stable for several hours after death under most circumstances but continues to rise in NPN toxicosis.

Diagnosis: Ammonia or NPN poisoning is suggested by signs, lesions, history of acute illness, and dietary exposure. Exposure to excess NPN may be evaluated through laboratory analysis for the ammonia nitrogen ($\text{NH}_3\text{-N}$) in both antemortem and postmortem specimens and for urea or other NPN in suspected feeds and other dietary sources. Specimens for $\text{NH}_3\text{-N}$ analysis include ruminal-reticular fluid, serum, whole blood, and urine. All specimens should be frozen immediately after collection and thawed only for analysis; alternatively, ruminal-reticular fluid may be preserved with a few drops of saturated mercuric chloride solution added to each 100 mL of specimen.

Animals dead more than a few hours in hot ambient temperatures or 12 hr in moderate climates probably have undergone too much autolysis to be of diagnostic value.

The amount of urea or the equivalent NPN in biologic specimens is meaningless; however, urea and NPN should be determined in representative feeds and other dietary sources. Values for urea and NPN in feed permit calculation of the protein equivalent (1 part protein = 0.36 parts urea; 1 part urea = 2.92 parts protein) in feed as well as the total estimated dose of NPN ingested.

$\text{NH}_3\text{-N}$ concentrations of ≥ 2 mg/100 mL in blood, serum, or vitreous humor indicate excess NPN exposure. Clinical signs usually appear at ~ 1 mg/100 mL. The concentration of $\text{NH}_3\text{-N}$ in ruminal-reticular fluid is >80 mg/100 mL in most cases of NPN poisoning and may be >200 mg/100 mL. Acclimated ruminants fed diets high in legume hay, soybean meal, cottonseed meal, linseed meal, fish meal, or milk byproducts may have $\text{NH}_3\text{-N}$ concentrations in rumen fluid approaching 60 mg/100 mL with no apparent toxicity. The pH of ruminal-reticular fluid should also be determined; a pH of 7.5–8 (at time of death) is indicative of NPN toxicity.

Differential diagnoses include poisonings by nitrate/nitrite, cyanide, organophosphate/carbamate pesticides, raw soybean overload, 4-methylimidazole, lead, chlorinated hydrocarbon pesticides, and toxic gases (carbon monoxide, hydrogen sulfide, nitrogen dioxide); acute infectious diseases; and noninfectious diseases such as encephalopathies (eg, leukoencephalomalacia, hepatic encephalopathy, polioencephalomalacia), enterotoxemia or rumen autointoxication, protein engorgement, grain engorgement, ruminal tympany, and pulmonary adenomatosis. Nutritional and metabolic disorders related to hypocalcemia, hypomagnesemia, and other elemental aberrations should also be considered.

Treatment: Examination and treatment may be difficult because of sudden and violent behavior. Animals that are recumbent and moribund usually do not respond favorably to treatment.

If possible, affected animals should be treated by ruminal infusion of 5% acetic acid (vinegar, 0.5–2 L in sheep and goats and 2–8 L in cattle). Ruminal-reticular fluid specimens for analysis should be taken before acetic acid therapy. Concomitant infusion of iced (0–4°C) water (up to 40 L in adult cattle, proportionally less in sheep and goats) is also recommended. Acetic acid lowers rumen pH and prevents further absorption of NH_3 by converting uncharged NH_3 to the charged ammonium ion (NH_4^+); administration may have to be repeated if affected animals again show clinical signs. Acetic acid inactivates existing NH_3 in the GI tract and rapidly forms ammonium acetate, which can be used by rumen microflora but does not release NH_3 . Cold water lowers the rumen temperature and dilutes the reacting media, which slows urease activity. In severely affected valuable animals, removed rumen contents should be replaced with a hay slurry, and a transfer of some rumen contents from a healthy animal may serve as an inoculum to restore normal function. Ruminal tympany should be corrected if indicated, and a trocar may be installed to prevent recurrence.

Supportive therapy is indicated and includes IV isotonic saline solutions to correct dehydration, and IV calcium gluconate and magnesium solutions to relieve tetanic seizures. Convulsions may also be controlled with sodium pentobarbital or other injectable anesthetic agents.

Prevention and Control: Urea should not be fed at a rate exceeding 2%–3% of the concentrate or grain portion of ruminant diets and should be limited to $\leq 1\%$ of the total diet. Additionally, NPN should constitute no more than one-third of the total nitrogen in the ruminant diet. Once the decision is made to feed NPN, animals must be slowly adapted to, and maintained on, a consistent dietary NPN content with no significant deviation; cows fed range cubes with NPN must receive the cubes daily with no interruptions. Temporary absences of NPN from the diet should be avoided at all costs. Overconsumption of palatable liquid supplements can be controlled by the addition of phosphoric acid; 1% phosphorus from phosphoric acid should restrict consumption of liquid supplement to ~2 lb/animal/day. Although properly adapted adult cattle can tolerate urea at a rate of up to 1 g/kg body wt/day, a safer feeding rate is no more than half that amount.

COAL-TAR PRODUCTS POISONING

A variety of coal-tar derivatives induce acute to chronic disease in animals, with clinical signs that vary based on the constituents. Clinical effects are acute to chronic hepatic damage with signs of icterus, ascites, anemia, and death. Phenolic components may cause renal tubular damage. Coal tar–related poisoning has been reported in farm animals and pets.

Etiology: The distillation of coal tar yields a variety of compounds, three of which are notably toxic: cresols (phenolic compounds), crude creosote (composed of cresols, heavy oils, and anthracene), and pitch. Tars are also produced from crude petroleum or wood. Creosote contains less volatile liquid and solid aromatic hydrocarbons of coal tar and some phenols. They have been used for restricted applications as wood preservatives. Cresols, composed mainly of

hydroxytoluenes, are used in soaps and disinfectants. Coal-tar and pine-tar pitch are the brown to black, amorphous, polynuclear hydrocarbon residues left after coal tar is redistilled. Access of animals to coal tars is often by direct chewing on or consumption of product, rather than inclusion in feed or water. Clay pigeons (older products), tar paper, creosote-treated wood, and bitumen-based flooring are typical sources.

Phenol is the most important toxicant in coal-tar products and is found in antiseptics, creosote, germicides, cleaners, and disinfectants. The approximate oral acute LD_{50} of phenol for most species is 0.5 g/kg, except for cats, which are more susceptible because of limited ability to form glucuronides and excrete phenols. Phenols are directly corrosive, and ingestion results in oral and upper gastroenteric necrosis. After oral or dermal absorption, phenols

accumulate in the liver and kidneys, commonly resulting in liver damage and renal tubular necrosis.

Cresols are readily absorbed orally and through the skin. The oral lethal dose is 100–200 mg/kg, except in cats, which are more sensitive. Sows in creosote-treated wooden farrowing crates delivered stillborn pigs. Coal tars may reduce absorption of vitamin A by sows. Other species are less susceptible (eg, the lethal dose of creosote in calves is 4 g/kg). Pitch is no longer used as a binder in clay pigeons, but road asphalt, some insulation, and tar paper and roofing compounds may still contain cresols. Flooring with lignite pitch or asphalt can reduce growth rate and/or cause liver damage in pigs.

Clinical Findings: The cresols and phenols are locally corrosive, causing necrosis and scarring of skin, mouth, and esophagus; CNS stimulation, tremors, and incoordination; and cardiovascular depression and shock. Capillary damage and hepatic or renal damage can occur. Icterus can result from intravascular hemolysis and hepatic damage. Death can occur from 15 min to several days after exposure. The first sign of pitch poisoning often is several dead animals. Signs may progress to weakness, ataxia, sternal recumbency, icterus, coma, and death. Secondary anemia may develop. Other problems have included stillbirths in pigs and hyperkeratosis in calves.

Lesions: Phenols, cresols, and creosote produce contact irritation of skin, mouth, and esophagus and nonspecific liver and kidney lesions. The liver is markedly swollen with a diffuse, mottled appearance. There is centrilobular liver necrosis, with blood replacing the lost cells and filling the center of the lobule. Renal tubular degeneration and

necrosis also can be present. The blood clots slowly or not at all. The carcass is icteric. Excessive fluid is found in the peritoneal cavity.

Diagnosis: Differential diagnoses include toxic plant poisonings (*Crotalaria*, *Senecio*, cocklebur), aflatoxicosis, blue-green algae poisoning, fumonisin toxicosis, gossypol toxicosis, yellow phosphorus poisoning, and vitamin E or selenium deficiency. Fragments of tar paper or other sources of coal tars found in the GI tract, or chemical detection of coal-tar products in liver, kidney, serum, or urine, aid in confirming the diagnosis. Laboratory changes include hypoglycemia, and increases in serum liver enzymes, thymol turbidity, chloride, and phosphorus. Proteinuria, hematuria, and urinary cells and casts reflect kidney damage from phenolic fractions of coal tars.

A rapid presumptive test is to mix 1 mL of urine with 0.1 mL of 20% ferric chloride; purple color indicates phenol, but results should be confirmed by a laboratory.

Treatment: There is no specific antidote for coal-tar product poisoning. Emetics and gastric lavage are not recommended for recent oral exposure, but activated charcoal and saline cathartics may reduce absorption. Owners may reduce acute exposure by administration of egg whites to dilute and bind the phenols. Dermal exposures are mitigated by bathing with glycerol followed by liquid dish soap. Supportive therapy for shock, liver and kidney damage, respiratory failure, and acidosis are important supportive measures for individual animals. *N*-acetylcysteine (140 mg/kg, IV, loading dosage, followed by 70 mg/kg, qid for another 3 days) has been recommended. Oral antibiotics, B vitamins, vitamin E, and high-quality-protein diets may aid recovery.

ETHYLENE GLYCOL TOXICITY

All animals are susceptible to ethylene glycol (EG) toxicity, but it is most common in dogs and cats. Most intoxications are associated with ingestion of antifreeze, which is typically 95% EG. These 95% commercial antifreeze preparations are diluted ~50% with water when used in vehicle cooling systems. The widespread

availability of antifreeze, its sweet taste and small minimum lethal dose, and the lack of public awareness of the toxicity (ie, improper storage and disposal) contribute to the frequency of this intoxication. In addition, antifreeze may be ingested by way of intentional poisoning or because it is the only available liquid in cold weather. Other

sources of EG include some heat-exchange fluids used in solar collectors and ice-rink freezing equipment and some brake and transmission fluids. Cutaneous absorption from topical products that contain EG has been reported to cause toxicity in cats.

EG intoxication occurs most commonly in temperate and cold climates, because antifreeze is used both to decrease the freezing point and to increase the boiling point of radiator fluid. In colder climates, the incidence of EG intoxications is seasonal, with most cases occurring in the fall, winter, and early spring, when antifreeze is added to radiator fluid or when cooling systems are flushed.

The minimum lethal dose of undiluted EG is 1.4 mL/kg body wt in cats, 4.4 mL/kg in dogs, 7–8 mL/kg in poultry, and 2–10 mL/kg in cattle. Younger animals may be more susceptible.

Pathogenesis: EG is rapidly absorbed from the GI tract; in dogs, blood concentrations of EG peak within 3 hr of ingestion. Approximately 50% of ingested EG is excreted unchanged by the kidneys; however, a series of oxidation reactions in the liver and kidneys metabolize the remaining EG. Toxic metabolites of EG cause severe metabolic acidosis and renal tubular epithelial damage.

The first of two rate-limiting biotransformation steps is the production of glycoaldehyde from EG by the enzyme alcohol dehydrogenase. Glycoaldehyde is then rapidly metabolized to glycolic acid. The oxidation of glycolic acid to glyoxylic acid is the second rate-limiting step, which allows glycolic acid to accumulate, resulting in acidosis and nephrotoxicosis. Glyoxylic acid is rapidly metabolized to formic acid, carbon dioxide, glycine, serine, and oxalate. Oxalate is not further metabolized and is cytotoxic to the renal tubular epithelium and exacerbates the metabolic acidosis. Glycolic acid and oxalate are the metabolites thought to be most responsible for acute tubular necrosis associated with EG ingestion. Oxalate also combines with calcium to form a soluble complex that is excreted via glomerular filtration. Calcium oxalate crystals form within the lumina of tubules as water is reabsorbed from the glomerular filtrate and the pH decreases (smaller numbers of calcium oxalate crystals may also be observed in the adventitia of blood vessel walls throughout the body).

Clinical Findings: Clinical signs are dose- and time-dependent and can be divided into

those caused by unmetabolized EG and those caused by its toxic metabolites. The onset of clinical signs is almost immediate and resembles alcohol (ethanol) intoxication. Dogs and cats exhibit vomiting due to GI irritation, polydipsia and polyuria, and neurologic signs (CNS depression, stupor, ataxia, knuckling, decreased withdrawal and righting reflexes). Polydipsia occurs due to osmotic stimulation of the thirst center, and polyuria occurs due to an osmotic diuresis and decreased production and release of antidiuretic hormone. As CNS depression increases in severity, dogs and cats drink less; however, the osmotic diuresis continues and results in dehydration. Dogs may appear to transiently recover from these CNS signs ~12 hr after ingestion.

Oliguric acute renal failure usually develops between 12 and 24 hr in cats and between 36 and 72 hr in dogs. Signs include lethargy, anorexia, dehydration, vomiting, diarrhea, oral ulcers, salivation, tachypnea, and possibly seizures or coma. The kidneys are often swollen and painful on abdominal palpation.

Pigs ingesting EG are usually depressed, weak, and reluctant to move; knuckling, posterior ataxia, trembling, collapse, abdominal distention, pulmonary edema, and muffled heart sounds are common sequelae. Poultry may become drowsy, ataxic, dyspneic, and recumbent; torticollis, ruffled feathers, and watery droppings are also seen. Cattle may become depressed, tachypneic, and ataxic, and develop paraparesis or recumbency. Epistaxis and hemoglobinuria have also been seen in cattle that have ingested large doses of EG.

Lesions: Renal tubular epithelial necrosis with calcium oxalate crystals in the tubular lumina is the characteristic finding of EG intoxication. Calcium oxalate crystals appear birefringent when viewed with polarized light. Pulmonary edema and hemorrhagic gastroenteritis are common secondary findings in dogs and cats. Pigs and cattle often develop renal and perirenal edema. Pigs may also have pulmonary edema with tan fluid in the pleural and peritoneal cavities. Poultry usually do not develop gross lesions.

Diagnosis: Diagnosis is often difficult because the nonspecific multisystemic signs may appear similar to other types of CNS disease or trauma, gastroenteritis, pancreatitis, ketoacidotic diabetes mellitus, and acute renal failure due to renal ischemia or other nephrotoxicants. If ingestion of EG is not witnessed, diagnosis is usually based on a combination of history, physical examination, and laboratory data.

Within 3 hr of ingestion of toxic doses of EG, dogs and cats develop normochloremic metabolic acidosis with an increased anion gap, minimally concentrated or isosthenuric urine with an acidic pH, and marked serum hyperosmolality with an increased osmolal gap. Serum osmolality can be increased as much as 100 mOsm/kg above normal (280–310 mOsm/kg) within 3 hr of EG ingestion. The difference between measured and calculated ($1.86 [Na^+ + K^+] + \text{glucose}/18 + \text{BUN}/2.8 + 9$) osmolality is referred to as the osmolal gap. The gap is caused by the presence of osmotically active particles (eg, ethylene glycol) in the serum that are not factored into the above equation. Calcium oxalate crystalluria may be observed as early as 3 and 6 hr after ingestion in cats and dogs, respectively. Monohydrate calcium oxalate crystals (clear, 6-sided prisms) are more common than dihydrate calcium oxalate crystals (maltese cross or envelope-shaped). EG concentrations in serum and urine are detectable by 1–2 hr after ingestion. Commercial test kits can detect serum EG concentrations of ≥ 50 mg/dL. Some antifreeze preparations contain fluorescein, which appears bright yellow-green when viewed under a Wood's lamp. Urine fluorescence has been used as a qualitative adjunctive test in suspected EG ingestions in people and may be of value in veterinary medicine. Hyperphosphatemia has been seen in dogs within 3 hr of ingestion of commercial antifreeze solutions that contain phosphate rust inhibitors. This hyperphosphatemia resolves before the onset of EG-induced acute renal failure and azotemia, then recurs when the animal becomes azotemic.

Treatment: The prognosis varies inversely with the amount of time that elapses between ingestion and initiation of treatment. Treatment is aimed at decreasing absorption of ingested EG, increasing excretion of unmetabolized EG, preventing metabolism of EG, and correcting the metabolic acidosis that occurs with EG metabolism. Further absorption of EG is prevented by induction of emesis or gastric lavage (or both) within 1–2 hr of ingestion, although the rapidity of EG absorption from the GI tract suggests these procedures may not be beneficial. Vomiting should not be induced in a dog or cat exhibiting neurologic signs because of increased risk of aspiration. Activated charcoal is not likely to reduce absorption of EG from the GI tract. Once absorption has occurred, excretion of EG is increased by fluid therapy designed to correct dehydration and increase urine production. To prevent metabolism of EG, the activity of

alcohol dehydrogenase is decreased by direct inactivation or by competitive inhibition. 4-Methylpyrazole (4-MP, fomepizole) effectively inactivates alcohol dehydrogenase in dogs without the adverse effects of ethanol and is the treatment of choice. The dose of 4-MP (5% solution [50 mg/mL]) is 20 mg/kg body wt, IV, initially, followed by 15 mg/kg, IV, at 12 and 24 hr, and 5 mg/kg, IV, at 36 hr. Commercial formulations of 4-MP are available. If 4-MP is not available, an ethanol regimen (5.5 mL of 20% ethanol/kg body wt, IV, every 4 hr for five treatments and then every 6 hr for four additional treatments) is recommended.

In cats, 4-MP is ineffective at the canine dosage, and either a higher, extra-label dosage (125 mg/kg initially, followed by 31.3 mg/kg at 12, 24, and 36 hr after the initial dose) or ethanol is used. The recommended dosage is 5 mL of 20% ethanol/kg body wt diluted in IV fluids and given as a drip over 6 hr for five treatments, and then over 8 hr for four more treatments.

The metabolic acidosis associated with metabolism of EG is corrected by administration of sodium bicarbonate. The formula $0.3 - (0.5 \times \text{kg body wt}) \times (24 - \text{plasma bicarbonate})$ is used to determine the dose, in mEq of bicarbonate. One-half of this dose should be given IV slowly to prevent overdose, and plasma bicarbonate concentrations should be monitored every 4–6 hr. Additional doses of bicarbonate based on the above formula are frequently necessary. Monitoring urine pH may also be helpful, with a goal of maintaining the urine pH between 7.0 and 7.5.

In dogs and cats with azotemia or in oliguric acute renal failure, inhibition of alcohol dehydrogenase is of little benefit, because almost all of the EG has already been metabolized. The prognosis for these animals is guarded to poor. Treatment should include correction of fluid, electrolyte, and acid-base disorders and, if possible, induction of diuresis.

PROPYLENE GLYCOL TOXICOSIS

Although less toxic than EG, ingestion of propylene glycol (PG) may be associated with a toxic syndrome similar to the acute phase of EG toxicosis. The oral LD_{50} of PG in dogs is ~ 9 mL/kg. In cats, ingestion of a diet containing 6%–12% PG can result in Heinz body formation and decreased RBC survival. Treatment of PG toxicosis is largely supportive—the use of alcohol dehydrogenase inhibitors is not indicated. Ingestion of PG may result in false-positive EG test kit results.

NITRATE AND NITRITE POISONING

Many species are susceptible to nitrate and nitrite poisoning, but cattle are affected most frequently. Ruminants are especially vulnerable because the ruminal flora reduces nitrate to ammonia, with nitrite (~10 times more toxic than nitrate) as an intermediate product. Nitrate reduction (and nitrite production) occurs in the cecum of equids but not to the same extent as in ruminants. Young pigs also have GI microflora capable of reducing nitrate to nitrite, but mature monogastric animals (except equids) are more resistant to nitrate toxicosis because this pathway is age-limited.

Acute intoxication is manifested primarily by methemoglobin formation (nitrite ion in contact with RBCs oxidizes ferrous iron in Hgb to the ferric state, forming stable methemoglobin incapable of oxygen transport) and resultant anoxia. Secondary effects due to vasodilatory action of the nitrite ion on vascular smooth muscle may occur. The nitrite ion may also alter metabolic protein enzymes. Ingested nitrates may directly irritate the GI mucosa and produce abdominal pain and diarrhea.

Although usually acute, the effects of nitrite or nitrate toxicity may be subacute or chronic and are reported to include retarded growth, lowered milk production, vitamin A deficiency, minor transitory goitrogenic effects, abortions and fetotoxicity, and increased susceptibility to infection. Chronic nitrate toxicosis remains a controversial issue and is not as yet well characterized, but most current evidence does not support assertions of lowered milk production in dairy cows due to excessive dietary nitrate exposure alone.

Etiology: Nitrates and nitrites are used in pickling and curing brines to preserve meats, and in certain machine oils and antirust tablets, gunpowder and explosives, and fertilizers. They may also serve as therapeutic agents for certain noninfectious diseases, eg, cyanide poisoning. Toxicoses occur in unacclimated domestic animals, most commonly from ingestion of plants that contain excess nitrate, especially by hungry animals engorging themselves and taking in an enormous body burden of nitrate. Confounding interactions with nonprotein nitrogen, monensin, and other feed components may exacerbate effects of

excessive nitrate content in livestock diets, especially when coupled with management errors.

Nitrate toxicosis can also result from accidental ingestion of fertilizer or other chemicals. Nitrate concentrations may be hazardous in ponds that receive extensive feedlot or fertilizer runoff; these types of nitrate sources may also contaminate shallow, poorly cased wells. Although nitrate concentrations are increasing in groundwater in the USA, well water is rarely the sole cause of excess nitrate exposure.

Water with both high nitrate content and significant coliform contamination has greater potential to adversely affect health and productivity than does either nitrate or bacteria alone. Livestock losses have occurred during cold weather due to the concentrating effect of freezing, which increases nitrate content of remaining water in stock tanks.

Crops that readily concentrate nitrate include cereal grasses (especially oats, millet, and rye), corn (maize), sunflower, and sorghums. Weeds that commonly have high nitrate concentrations are pigweed, lamb's-quarter, thistle, Jimson weed, fireweed (*Kochia*), smartweed, dock, and Johnson grass. Anhydrous ammonia and nitrate fertilizers and soils naturally high in nitrogen tend to increase nitrate content in forage.

Excess nitrate in plants is generally associated with damp weather conditions and cool temperatures (55°F [13°C]), although high concentrations are also likely to develop when growth is rapid during hot, humid weather. Drought conditions, particularly if occurring when plants are immature, may leave the vegetation with high nitrate content. Decreased light, cloudy weather, and shading associated with crowding conditions can also cause increased concentrations of nitrates within plants. Well-aerated soil with a low pH, and low or deficient amounts of molybdenum, sulfur, or phosphorus in soil tend to enhance nitrate uptake, whereas soil deficiencies of copper, cobalt, or manganese tend to have opposing effects. Anything that stunts growth increases nitrate accumulation in the lower part of the plant. Phenoxo acid derivative herbicides (eg, 2,4-D and 2,4,5-T), applied to nitrate-accumulating plants during early stages,

cause increased growth and a high nitrate residual (10%–30%) in surviving plants, which are lush and eaten with apparent relish even though previously avoided.

Nitrate, which does not selectively accumulate in fruits or grain, is found chiefly in the lower stalk with lesser amounts in the upper stalk and leaves. Nitrate in plants can be converted to nitrite under the proper conditions of moisture, heat, and microbial activity after harvesting.

Clinical Findings: Signs of nitrite poisoning usually appear suddenly because of tissue hypoxia and low blood pressure as a consequence of vasodilation. Rapid, weak heartbeat with subnormal body temperature, muscular tremors, weakness, and ataxia are early signs of toxicosis when methemoglobinemia reaches 30%–40%. Brown, cyanotic mucous membranes develop rapidly as methemoglobinemia exceeds 50%. Dyspnea, tachypnea, anxiety, and frequent urination are common. Some monogastric animals, usually because of excess nitrate exposure from nonplant sources, exhibit salivation, vomiting, diarrhea, abdominal pain, and gastric hemorrhage. Affected animals may die suddenly without appearing ill, in terminal anoxic convulsions within 1 hr, or after a clinical course of 12–24 hr or longer. Acute lethal toxicoses almost always are due to development of $\geq 80\%$ methemoglobinemia.

Under certain conditions, adverse effects may not be apparent until animals have been eating nitrate-containing forages for days to weeks. Some animals that develop marked dyspnea recover but then develop interstitial pulmonary emphysema and have continued respiratory distress; most of these recover fully within 10–14 days. Abortion and stillbirths may be seen in some cattle 5–14 days after excessive nitrate/nitrite exposure but likely only in cows that have survived a $\geq 50\%$ methemoglobinemia for 6–12 hr or longer. Prolonged exposure to excess nitrate coupled with cold stress and inadequate nutrition may lead to the alert downer cow syndrome (see p 188) in pregnant beef cattle; sudden collapse and death can result.

Lesions: Blood that contains methemoglobin usually has a chocolate-brown color, although dark red hues may also be seen. There may be pinpoint or larger hemorrhages on serosal surfaces. Hydroperitoneum and ascites have been reported in stillborn calves, as well as edema and hemorrhage in the lungs and digestive system of perinatal calves with excessive maternal nitrate exposure. However, dark

brown discoloration evident in moribund or recently dead animals is not pathognomonic, and other methemoglobin inducers must be considered. If necropsy is postponed too long, the brown discoloration may disappear with conversion of methemoglobin back to Hgb.

Diagnosis: Excess nitrate exposure can be assessed by laboratory analysis for nitrate in both pre- and postmortem specimens. High nitrate and nitrite values in postmortem specimens may be an incidental finding, indicative only of exposure and not toxicity. Plasma is the preferred pre-mortem specimen, because some plasma protein-bound nitrite could be lost in the clot if serum was collected. Nitrite present in whole blood also continues to react with Hgb *in vitro*, so these specimens must be centrifuged immediately and plasma separated to prevent erroneous values of both. Additional postmortem specimens from either toxicoses or abortions include ocular fluids, fetal pleural or thoracic fluids, fetal stomach contents, and maternal uterine fluid. All specimens should be frozen in clean plastic or glass containers before submission, except when whole blood is collected for methemoglobin analysis. Because the amount of nitrate in rumen contents is not representative of concentrations in the diet, evaluation of rumen contents is not indicated.

Bacterial contamination of postmortem specimens, especially ocular fluid, is likely to cause conversion of nitrate to nitrite at room temperature or higher; such specimens may have abnormally high nitrite concentrations with reduced to absent nitrate concentrations. Endogenous biosynthesis of nitrate and nitrite by macrophages stimulated by lipopolysaccharide or other bacterial products may also complicate interpretation of analytical findings; this should be considered as a possible maternal or fetal response to an infection.

Methemoglobin analysis alone is not a reliable indicator of excess nitrate or nitrite exposure except in acute toxicosis, because 50% of methemoglobin present will be converted back to Hgb in ~ 2 hr, and alternative forms of nonoxygenated Hgb that may be formed by reaction with nitrite are not detected by methemoglobin analysis. Nitrate and nitrite concentrations >20 mcg NO_3/mL and >0.5 mcg NO_2/mL , respectively, in maternal and perinatal serum, plasma, ocular fluid, and other similar biologic fluids are usually indicative

of excessive nitrate or nitrite exposure in most domestic animal species; nitrate concentrations of up to 40 mcg NO_3/mL have been present in the plasma of healthy calves at birth but are reduced rapidly as normal neonatal renal function eliminates nitrate in the urine. In acutely poisoned ruminant livestock, nitrate and nitrite concentrations as high as 300 mcg NO_3/mL and 25–50 mcg NO_2/mL , respectively, can be found in plasma or serum, with $\sim 1/3$ less in postmortem ocular fluid because of diffusion equilibrium delay. However, postmortem ocular fluid nitrate concentrations are relatively stable and remain diagnostically significant for up to 60 hr after death. Once collected, plasma, serum, and ocular fluid specimens have stable nitrate concentration for at least 1 mo at -20°C .

Normally expected nitrate and nitrite concentrations in similar diagnostic specimens are usually <10 mcg NO_3/mL and <0.2 mcg NO_2/mL , respectively. Nitrate and nitrite concentrations >10 but <20 mcg NO_3/mL and >0.2 but <0.5 mcg NO_2/mL , respectively, are suspect and indicate nitrate or nitrite exposure of unknown duration, extent, or origin. The possible contribution of endogenous nitrate or nitrite synthesis by activated macrophages must also be considered. The biologic half-life of nitrate in beef cattle, sheep, and ponies was determined to be 7.7, 4.2, and 4.8 hr, respectively, so it will be at least five biologic half-lives (24–36 hr) before increased nitrate concentrations from excessive nitrate exposure diminish to normally expected values, allowing additional time for valid pre-mortem specimen collection.

A latent period may exist between excessive maternal dietary nitrate exposure and equilibrium in perinatal ocular fluids. Aqueous humor is actively secreted into the anterior chamber at a rate of $\sim 0.1/\text{mL}/\text{hr}$, and nitrate and nitrite are thought to enter the globe of the eye by this mechanism. Equilibrium between aqueous and vitreous humor is by passive diffusion rather than by active secretion, so nitrate or nitrite may be present in comparatively lesser concentrations in vitreous humor after acute exposure.

Field tests for nitrate are presumptive and should be confirmed by standard analytical methods at a qualified laboratory. The diphenylamine blue test (1% in concentrated sulfuric acid) is more suitable to determine the presence or absence of nitrate in suspected forages. Nitrate test strips (dipsticks) are effective in determining nitrate values in water supplies and can

be used to evaluate nitrate and nitrite content in serum, plasma, ocular fluid, and urine.

Differential diagnoses include poisonings by cyanide, urea, pesticides, toxic gases (eg, carbon monoxide, hydrogen sulfide), chlorates, aniline dyes, aminophenols, or drugs (eg, sulfonamides, phenacetin, and acetaminophen), as well as infectious or noninfectious diseases (eg, grain overload, hypocalcemia, hypomagnesemia, pulmonary adenomatosis, or emphysema) and any other cause of sudden unexplained deaths.

Treatment: Slow IV injection of 1% methylene blue in distilled water or isotonic saline should be given at 4–22 mg/kg or more, depending on severity of exposure. Lower dosages may be repeated in 20–30 min if the initial response is not satisfactory. Lower dosages of methylene blue can be used in all species, but only ruminants can safely tolerate higher dosages. If additional exposure or absorption occurs during therapy, re-treating with methylene blue every 6–8 hr should be considered. Rumen lavage with cold water and antibiotics may stop the continuing microbial production of nitrite.

Control: Animals may adapt to higher nitrate content in feeds, especially when grazing summer annuals such as sorghum-Sudan hybrids. Multiple, small feedings help animals adapt. Trace mineral supplements and a balanced diet may help prevent nutritional or metabolic disorders associated with long-term excess dietary nitrate consumption. Feeding grain with high-nitrate forages may reduce nitrite production. However, caution is advised when combining other feed additives/components, including nonprotein nitrogen, ionophores (such as monensin) and other growth and performance enhancers, with high-nitrate diets in ruminants. Proper management, especially regarding acclimation, is critical. Forage nitrate concentrations $>1\%$ nitrate dry-weight basis (10,000 ppm NO_3) may cause acute toxicoses in unacclimated animals, and forage nitrate concentrations $\leq 5,000$ ppm NO_3 (dry-weight basis) are recommended for pregnant beef cows. However, even forage concentrations of 1,000 ppm NO_3 dry-weight basis have been lethal to hungry cows engorging themselves in a single feeding within an hour, so the total dose of nitrate ingested is a deciding factor.

High-nitrate forages may also be harvested and stored as ensilage rather than dried hay or green chop; this may reduce the

nitrate content in forages by up to 50%. Raising cutter heads of machinery during harvesting operations selectively leaves the more hazardous stalk bases in the field.

Hay appears to be more hazardous than fresh green chop or pasture with similar nitrate content. Heating may assist bacterial conversion of nitrate to nitrite; feeding high-nitrate hay, straw, or fodder that has been damp or wet for several days, or stockpiled, green-chopped forage should

be avoided. Large round bales with excess nitrate are especially dangerous if stored uncovered outside; rain or snow can leach and subsequently concentrate most of the total nitrate present into the lower third of these bales.

Water transported in improperly cleaned liquid fertilizer tanks may be extremely high in nitrate. Young, unweaned livestock, especially neonatal pigs, can be more sensitive to nitrate in water.

PENTACHLOROPHENOL POISONING

(Penta poisoning)

Pentachlorophenol (PCP), commonly known as penta, has been used as a fungicide, molluscicide, insecticide, and wood preservative. Its use is now permitted only for industrial purposes; agricultural and domestic uses are prohibited, because it is classified as a highly hazardous pesticide.

The oral LD₅₀ of penta in rats is 150–210 mg/kg body wt. Common signs of poisoning include nervousness, rapid pulse and respiratory rate, weakness, fever, muscle tremors, convulsions, loss in righting reflexes, and asphyxial spasms followed by death. Corneal injury may result from splashes or vapor overexposure. Chronic poisoning results in emaciation, fatty liver, nephrosis, and weight loss.

The persistence of penta in soil and water and apparent widespread use has resulted in significant exposure to animals. Young swine have died after dermal exposure to freshly penta-treated wood used in farrowing crates or farrowing houses. In vivo studies in swine demonstrated that exposure to penta-contaminated soil can result in significant dermal absorption of the pesticide. Penta can be absorbed through intact skin and lungs and is an intense irritant to the skin and mucous membranes. Penta absorption in skin was greater in water or water-based mixtures than in 100% ethanol. Because animals typically have access to water at all times, this hydrophilic characteristic of penta suggests enhanced dermal absorption.

When absorbed, penta increases metabolism by uncoupling cellular phosphorylation. Animals fed in troughs

made of lumber treated with PCP may salivate and have irritated oral mucosa. Both penta and its major metabolite, tetrachlorohydroquinone (TCHQ), can induce epidermal hyperplasia in mice.

Poultry have been exposed to sawdust and shavings from penta-treated wood. Associated adverse effects include reduced growth rates, kidney hypertrophy, and decreased humoral immune response. Penta exposure can also result in an off-taste to eggs and meat as a result of degradation of chlorophenols to chloroanisols. Vaporization or leaching of penta in pens, enclosures, homes, and barns has caused illness and death.

Cattle and pigs exposed to wood treated with commercial grade penta had increased mortality, possibly decreased fertility in boars, and reduced productivity (milk, meat, etc). The lethal dose in cattle and sheep is ~120–140 mg/kg body wt.

Commercial lots of technical-grade penta contain small but biologically significant amounts of highly toxic impurities such as chlorinated dioxins and dibenzofurans, tetrachlorophenols, and hydroxychlorodiphenyl ethers; these compounds can exert their own effects such as early fetotoxicity. Commercial-grade penta causes hepatic porphyria, increased microsomal monooxygenase activity, and increased liver weight. Pure penta was not teratogenic in rats.

Penta can cause residues in animal tissues. Also, a significant amount of hexachlorobenzene is metabolized in animal tissues to penta. Pentachlorophenol is considered to be a carcinogen and a tumor promoter, although studies have

shown that the pure material does not increase the incidence of tumors in rats and mice. The technical-grade material has also been shown to be immunotoxic in laboratory studies. Penta must be handled very carefully and kept away from animal contact.

Whole blood analysis for penta may aid in the diagnosis of poisoning; diagnosis is usually made on the basis of the signs and the proximity of treated lumber in the animal's environment.

There is no known antidote. Termination of exposure, bathing dermally exposed animals, oral administration of activated charcoal, and supportive therapy may be indicated. Bathing should be done gently with cold water and detergent so as not to cause vasodilation and increased absorption. Antipyretics, eg, aspirin and acetaminophen, should not be used. Treatment involves cooling the animal and administering fluids, electrolytes, and anticonvulsants.

PETROLEUM PRODUCT POISONING

Ingestion or inhalation of, or skin contact with, petroleum, petroleum condensate, gasoline, diesel fuel, kerosene, crude oil, or other hydrocarbon mixtures may cause illness and occasionally death in domestic and wild animals. Dogs and cats both may ingest petroleum products during grooming of contaminated fur or directly from open containers. Inhalation may occur in poorly ventilated areas where these chemicals have been used or stored. Ruminants may ingest such products in large amounts because they are thirsty, curious, or seeking salt or other nutrients, or if food or water is contaminated.

Small quantities of petroleum product used as carriers for insecticides have few or no harmful effects, but large quantities and prolonged exposure can induce severe reactions. Pipeline breaks, accidental release from storage, tank car accidents, and open or leaky containers are potential sources. Physical properties can affect exposure and toxicity. Volatility increases at lower molecular weight and lower saturation or aromaticity. Absorption is greater with highly volatile, lower molecular weight hydrocarbons (eg, hexane, gasoline) as well as aromatic hydrocarbons (benzene, toluene) because of greater lipid solubility. Crude petroleum that has lost much of its lighter, more volatile components through weathering may still be hazardous.

Crude oil and gasoline contain varying amounts of aromatic hydrocarbons, including benzene (2%–5% in gasoline), toluene, ethylbenzene, and xylene. These compounds ingested or inhaled in sufficient amounts can have acute and chronic effects

different from those of other hydrocarbons that make up most oil and gas products. Benzene is hemotoxic and a known carcinogen at high levels of exposure. Toluene causes neurologic signs and damage at high dosages. Central nervous signs occur when sufficient petroleum product is absorbed into the brain or peripheral nerves. Toxicosis generally occurs rapidly after exposure.

Variation in composition of petroleum and petroleum-derived hydrocarbon mixtures explains some of the differences in toxic effects. Mixtures of low viscosity/high volatility (eg, gasoline, naphtha, kerosene, xylene) have a high aspiration hazard and irritant activity on pulmonary tissues. Gasoline and naphtha fractions may induce vomiting, which contributes to aspiration hazard. Fractions more viscous than kerosene (asphalt, mineral oil, waxes) are less likely to be inhaled and, even if aspirated, are somewhat less damaging to lung tissue. Older formulations of lubricating oils and greases can be particularly hazardous because of toxic additives or contaminants (eg, lead).

Comparative toxicity of petroleum hydrocarbons can be considered high (oral $LD_{50} < 10$ mL/kg, eg, acetone, benzene, carbon disulfide, diesel fuel, toluene, xylene), moderate (oral LD_{50} 10–20 mL/kg, eg, diesel fuel, gasoline, heating oil, isopropanol, turpentine), or limited (oral $LD_{50} > 20$ mL/kg, eg, motor oil, jet fuel, lighter fluid). Toxicity of crude oil depends on the relative content of kerosene, naphtha, and gasoline. Sweet crude oil (high gasoline, naphtha, and

kerosene content) at ~50 mL/kg and sour crude oil (low fractions of gasoline, naphtha, and kerosene) at 75 mL/kg exposure for 1 wk have caused aspiration pneumonia.

Clinical Findings: Petroleum hydrocarbon toxicity may involve the respiratory, GI, or integumentary systems or the CNS. In most cases of ingestion, no clinical signs are seen, but small animals are reported to show oral irritation, salivation, and champing of jaws, followed by coughing, choking, and vomiting. Pneumonia due to aspiration of hydrocarbons into the lungs is usually the most serious consequence of ingestion of these materials. Aspiration can occur during vomiting by monogastrics or eructation of rumen contents. Pulmonary damage can occur from a combination of volatility, viscosity, and surface tension. Higher volatility promotes access of vapors to the lung and airways and displaces alveolar oxygen. Risk of pulmonary toxicity is increased by products of lower viscosity and surface tension, with increased penetration into smaller airways and spread of product to a larger lung surface area.

Acute bloat from petroleum products in ruminants has been reported after consumption of highly volatile hydrocarbons such as gasoline or naphtha. CNS signs may be a result of the anesthetic-like action of low-molecular-weight aliphatic hydrocarbons and/or cerebral anoxia that can result from lung damage or displacement of oxygen by the more volatile hydrocarbons. Some compounds when absorbed in high doses may sensitize the myocardium to endogenous catecholamines. Anorexia, decreased rumen motility, and mild depression may begin in ~24 hr and last 3–14 days depending on dose and content. Hypoglycemia may be seen several days after ingestion. These signs and weight loss may be the only responses seen in animals that do not bloat or aspirate oil. Some animals do not reestablish normal rumen function after ingestion and can develop a chronic wasting condition.

After ingestion of oil, the feces may not be affected until several days later, when they become dry and formed, in the case of kerosene or lighter hydrocarbon fractions; in contrast, heavier hydrocarbon mixtures (eg, motor oil) tend to be cathartic. Oil may be found in feces and rumen contents as long as 2 wk after ingestion. Regurgitated or vomited oil may be seen on the muzzle and lips.

CNS signs attributable to pulmonary, dermal, or GI absorption of hydrocarbons or cerebral anoxia include excitability (associated with aromatic fractions—benzene, toluene, etc), depression (aliphatic or saturated low-molecular-weight hydrocarbons), shivering, head tremors, visual dysfunction (sometimes associated with lead contamination), and incoordination. Acute pneumonia and possibly pleuritis (coughing, tachypnea, shallow respiration, reluctance to move, head held low, weakness, oily nasal discharge, and dehydrated appearance) are seen in some animals that aspirate highly volatile mixtures; deaths usually are seen within days. Respiratory signs may be limited to dyspnea shortly before death in animals that aspirate heavier hydrocarbons. Increased PCV, Hgb, and BUN, indicating mild to moderate hemoconcentration, are associated with development of pneumonia. Neutropenia, lymphopenia, and eosinopenia occur initially and are followed by a relative increase in neutrophils.

There are a few anecdotal reports of abortion after exposure. Laboratory data in rodents support the occurrence of increased fetal loss and decreased fetal growth. However, the doses necessary to affect the fetus were also sufficient to profoundly affect maternal health and weight.

Lesions: Aspiration pneumonia is the most consistent postmortem finding in animals that do not die of bloat. This may be accompanied by tracheitis, pleuritis, and hydrothorax if highly volatile fractions such as gasoline or naphtha are involved. Lung lesions are usually bilateral and found in the caudoventral apical, cardiac, cranioventral diaphragmatic, and intermediate lobes. Affected portions are dark red and consolidated and may contain multiple abscesses. Encapsulated pulmonary abscesses may be found in cattle surviving up to several months after aspiration. Skin lesions may be obvious after repeated topical application or severe exposure and include drying, cracking, or blistering.

Diagnosis: A hydrocarbon odor may be detected in lungs, ruminal contents, and feces. Even if ingested in large doses, hydrocarbons may not be visible in ruminal contents after ~4 days. Adding warm water to the GI contents may cause any oily contents to collect at the surface, but finding oil in the GI tract does not in itself justify a diagnosis of poisoning; most oils have low toxicity if not aspirated. Sam-

ples of GI contents, lung, liver, kidney, and the suspected source should be collected for chemical analysis to demonstrate presence of hydrocarbons in tissue (particularly lung) and GI contents and to match those found in tissues and ingesta with the suspected source. Samples must be carefully protected from cross-contamination during necropsy and transportation to the laboratory. Instructions from the receiving diagnostic laboratory should be checked to ensure collection equipment and transport containers are appropriate to prevent evaporative loss of important components and contamination. Positive chemical findings together with appropriate clinical and pathologic findings are confirmatory. Diagnosis in oil-field situations has historically been complicated by involvement of other toxicants, eg, explosives, lead from grease and "pipe dope," arsenicals, organophosphate esters, caustics (acids or alkalis), and saltwater.

Treatment: Bloat pressure should be released by passing a stomach tube if absolutely necessary to save the life of the animal; using a trocar risks forcing oil into the peritoneal cavity, which results in peritonitis. Passing a stomach tube dramatically increases the risk of aspiration, and extreme caution is necessary. In the absence of bloat, the prime objectives are to prevent aspiration and to mitigate GI dysfunction. Rumenotomy to remove ruminal contents and replace them with healthy ruminal material is safer. More chronic cases involving primarily hypofunction of the rumen may also respond to this procedure. Cathartics, if used, should be of the saline or sorbitol type; however, there is no evidence that they improve prognosis. Recent information no longer supports use of oil-based cathartics for petroleum ingestion.

Activated charcoal has occasionally been suggested for use in small animals. Although it does not effectively adsorb petroleum distillates, it may be given if necessary to adsorb additives and other contaminants. Gastric lavage is generally contraindicated for petroleum and volatile hydrocarbon ingestions. Care should be taken to avoid inducing vomiting and aspiration. Small animals with acute respiratory distress may require supplemental oxygen and positive-pressure ventilation, used cautiously because of existing physical pulmonary damage. Frequent purging of ventilators is necessary to eliminate volatile hydrocarbons.

Animals with evidence of bacterial respiratory infection may require broad-spectrum antibiotic treatment. Pathogens can be introduced into the lungs from aspirated rumen or stomach contents mixed with the hydrocarbons. However, the use of steroids in hydrocarbon aspiration may further reduce the chance of recovery and are generally contraindicated. Treatment of aspiration pneumonia (*see* p 1417) is rarely effective, and the prognosis is poor. However, because signs of aspiration may not appear for several days, prognosis based on initial clinical findings may be misleading.

Most high-molecular-weight compounds pass through the GI tract unchanged. Most of the petroleum hydrocarbons are highly lipophilic and will be stored for varying times in tissues with high lipid content, including fat, nervous tissue, and the liver. Some of the absorbed compounds are metabolized into more toxic by-products (eg, benzene, toluene, and n-hexane). Although most of these compounds do not remain in the body for prolonged periods, little is known about exactly how long tissue levels persist in highly exposed animals. The potential for tissue residues must be considered before the slaughter of animals intended for human consumption.

In poisoning or damage due to cutaneous exposure, the material should be removed from the skin with the aid of soap or mild detergents and copious amounts of cool water. The skin should not be brushed or abraded. Further treatment depends on the clinical signs and is largely restricted to supportive therapy.

Petroleum hydrocarbon poisoning can be avoided only by preventing access to these materials through proper storage of home and farm chemicals and well-maintained fencing around high-risk petroleum facilities.

Effects of Oil and Gas Fields on Cattle Health and Production:

Anecdotal reports in the literature have documented producer concerns about the effect of oil fields on cattle health and production. Some observational studies have suggested that exposure to emissions from sour gas processing plants and sour gas flares (natural gas containing hydrogen sulfide) may be associated with an increased risk of certain reproductive losses in cattle. Researchers are currently reexamining these findings and exploring the impact of oil and gas field emissions on the immune system.

PERSISTENT HALOGENATED AROMATIC POISONING

Persistent halogenated hydrocarbons (PHAs) are manmade chemicals and can be products of incomplete combustion. PHAs are a complex mixture of chemicals with differing molecular composition. Some PHAs are added to consumer products to provide unique properties and have been/are used as pesticides and disinfection agents. Most PHAs persist in the environment and are classified as persistent organic pollutants. PHAs cause acute and chronic toxicity. There is evidence that lifetime chronic toxicity can be expressed differently during life stages from embryogenesis to senility. Exposure at early life stages may not be expressed until a later life stage. PHAs can be biomagnified in body fat and liver, translocated to the fetus, and secreted in milk and eggs. Biomagnification is a process wherein PHAs are concentrated in fat and liver at a factor higher than dietary levels and is a food safety issue. Important groups of PHAs include polybrominated diphenyl ethers (PBDEs), polychlorinated dibenzo-p-dioxins, dibenzofurans (PCDD/Fs), polychlorinated biphenyls (PCBs), DDT, and triclosan.

Etiology: Exposure to PHAs results from contamination of the indoor environment, especially house dust, atmospheric deposition of PHAs, amending agricultural lands with sewage sludge and industrial wastes, industrial incidents, and feed contamination including byproduct ingredients. Indoor dust is an important route of exposure of companion animals to PBDE fire retardants. For the other PHAs, diet is generally considered the primary route of exposure. Atmospheric PHAs, dispersed worldwide, tend to have higher concentrations in the arctic and antarctic regions. Atmospheric PHAs are deposited on soil and forages. Consumption of contaminated forage and soil by ruminants is a significant source of PCDD/Fs and other PHAs in the food web. Animal by-products containing PHAs, previously biomagnified in fat and liver by other animals in the food web, are also an important source of PHAs in animal diets. Ball clay contaminated with PCDDs has been incorporated in the diets of food-producing animals, and contaminated clay has been used in human food processing. Exposure assessments must include all sources of PHAs. Human dietary exposure

to PHAs is generally from ingestion of ruminant products and farmed and wild fish. Cats, like small children, are also exposed in the indoor environment.

Soil can be contaminated by industrial activity and spreading of waste materials on land. For example, spreading sewage sludge on soil can cause a 50× increase in the soil levels of PCDDs. Levels of PBDEs in sewage sludge have been reported as high as 2.3 ppm (dry), and the most consistent PBDE in sewage sludge is the penta-PDE. The primary source of the PCDD/Fs in forages harvested from contaminated soils is incorporated soil. Grass silages generally contain more PCDD/Fs than corn (maize) silage. The congener profile in forages can be used to chemically "fingerprint" the sources. Birds and other animals consume soil by geophagy when feeding. Grazing cattle and sheep can consume up to 17% and 30%, respectively, of the dry matter intake as soil. Ruminants and horses can also be exposed to PHAs by direct atmospheric deposition on vegetation. Atmospheric levels of PHAs generally vary with the season.

Companion animals have indoor environmental exposures to PHAs, especially the PBDEs, and cats are studied as a model to assess infant/toddler exposure. The PBDEs are a chemical mixture of congeners solubilized in plastics, carpets and other synthetic fabrics and foams, and electronic equipment to retard combustion. They contaminate indoor air as a vapor, migrate from carpets and other synthetic fibers, and are a component of house dust. PBDEs can also leach from products after disposal. The PBDEs with a lower bromination number generally are more environmentally persistent in food webs. The higher brominated PBDEs can be debrominated by biota to lower brominated PBDEs. Burning plastics containing PBDEs forms polybrominated dibenzo-p-dioxins (PBDDs) and dibenzofurans (PBDFs). The PBDD/Fs have toxicity similar to that of their chlorinated analogues and have been measured in adipose tissue. Triclosan, a polychlorinated hydroxydiphenyl ether, is widely used as a broad-spectrum bactericide and is an ingredient in many cleaning agents and hygiene products. Surfaces of products such as cutting boards, food wrappers, refrigerator linings, and cat litter can be

impregnated with triclosan for bactericidal action and to reduce odors. PHAs can be present in feedstuffs fed to dogs and cats. For example, fish oil, which may be used in formulated diets, generally is 2-fold higher in PCDD/Fs than in meat and bone meal.

Biomagnification, Translocation, and Food Safety:

PHAs are readily absorbed from the gut, lungs, and through the skin. After absorption, they can be biomagnified in body fat and the liver, translocated to the fetus, and excreted in milk and eggs. Food-producing animals can relay PHAs in foods and animal by-products. PHAs are in rendered animal products, including fat, bone, and meat meals. After absorption, the congener profile can be altered by biotransformation, with the congener profile in tissues and edible animal products different from the PHAs absorbed. The congeners translocated to the fetus can be different from the congeners deposited in fat. Toxicity can vary with the congener profile. Biomagnification of PHAs has been estimated for chickens and pigs. PHAs analyzed in chicken fat had biomagnification factors ranging from 7 to 35. For pigs, biomagnification factors ranging from <7 to 15 were observed. Lactating and egg-laying females generally have a lower body burden of PHAs. The PHA levels in milk generally are higher during the early part of the first lactation. In rainbow trout, ~30% of the dietary PCDD/Fs are transferred to fat located in muscle tissue. The biomagnification factor generally varies between PHAs, animal species, and food webs.

Toxicology: Studies have shown that people and domestic and wild animals are exposed to a chemical soup of PHAs throughout a lifetime. The possible antagonistic, additive, synergistic, and potentiating interactions of the PHAs in the mixture are not well known.

PHA groups and individual PHAs are potent up- and down-regulators of enzyme systems by interaction with immunotoxic nuclear receptors; some PHAs interact with an assortment of endocrine receptors. Cell signaling can also be disrupted. Exposure begins during embryologic development and continues with possible differing toxic effects occurring during development, maturation, and aging. For some effects, toxicity occurring at one life stage may not be expressed until the next life stage. The general toxicology includes disruption of the immune and endocrine systems and associated organs/functions. Immunotoxicity is considered a sensitive parameter for

some PCBs and TCDD/Fs congeners. The overall immune effect is reduced native resistance to infectious disease and a likely increased risk of neoplasia. The best-studied immunotoxic effect of PHAs is on the lymphocytes and acquired immunity. An abnormal increase in occurrences of infectious diseases can be observed in affected animals.

PHAs can alter endocrine functions. The US National Toxicology Program Workshop Review concluded there is evidence to support an association between selected exposure to PHAs and type 2 diabetes in people. Studies suggest that some PHAs may act as obesogens. There is growing general consensus that increased diagnosis of obesity in companion animals cannot be fully explained by genetics, lifestyle, and nutrition. Cats with lower capacity to metabolize PCBs have increased risk of acromegaly. In cats, an association between diabetes and PHA exposure has not been demonstrated in the studies published. Some PHAs are known to have an effect on thyroid endocrinology. The PHAs that induce hepatic uridine diphospho-glucuronosyltransferase or sulfotransferase isozymes increase biliary excretion of conjugated thyroid hormones. Some PCBs or their metabolites may interfere with binding of thyroid hormones to transporter proteins and the nuclear receptor. Exposure in utero to PCBs can increase brain deiodinases and may be a compensatory response to maintain tissue T_3 concentrations due to decreased fetal circulating and brain concentrations of T_4 . There is an association between high levels of PBDEs in house dust and hyperthyroidism in cats. Blood levels of PHAs have not been associated with hyperthyroidism in cats. The PBDEs have been shown in laboratory studies to disrupt thyroid function in mice and American kestrels. One mechanism appears to be competitive displacement of T_4 from its carrier protein by hydroxylated PBDE metabolites. Tetrabromobisphenol A has been shown to alter the thyroid hormone receptor. There is evidence that triclosan disrupts thyroid function.

PHAs can be steroid hormonal agonists and antagonists and can disrupt endocrine homeostasis. These disruptions can cause reproductive dysfunctions. A study on PCBs in cattle tissues showed that the stimulatory effects of follicle-stimulating hormone and luteinizing hormone on luteal, granulosa, and thecal cells were decreased for secretion of progesterone, estradiol, and testosterone, respectively. Using cattle uterine strips, PCBs have been shown to

increase the force of myometrial contractions and increase endometrial section of prostaglandin $F_{2\alpha}$. Exposure to PCBs and brominated biphenyls can delay onset of parturition in cattle.

There is increasing concern that some PHAs can alter hormonal function in utero. Exposure to PHAs in utero may alter body mass index and sexual functions later in life. Pre- and postnatal exposure to PHAs, through endocrine disruption mechanisms, may alter manmary gland development and function and increase the risk of manmary diseases. Goats exposed to PCBs in utero had altered adenyl function that varied with age and sex. The goats had lower basal cortisol levels during prepubertal development, and this effect persisted during their first breeding season. Male goats at 9 mo of age had a greater and prolonged rise in plasma cortisol levels when subjected to moderate stress.

PHAs can up-regulate the activities of cytochrome CYP (P450) and other enzymes. Changes in drug metabolism can occur. Changes in CYP activity can increase the formation of the ultimate toxicant of a variety of toxic substances. PHAs can also be promoters of carcinogens.

Clinical Findings, Lesions, and

Diagnosis: In chickens, acute exposure to PHAs may cause a sudden drop in egg production followed by reduced egg hatchability. Ascites and edema may be seen, together with ataxia. Lesions include degenerative changes in skeletal and cardiac muscle. Altered thyroid function is associated with anomalous development in birds and mammals.

In cats, acromegaly appears to be linked to a decreased ability to metabolize PCB congeners. Hyperthyroidism in cats is associated with high levels of PBDEs in house dust. Feeding mink or whale blubber, naturally contaminated with PHAs and other pollutants, to sled dogs was shown to increase occurrences of diffuse thickening of the glomerular capillary wall and Bowman's basement membranes. Tubular hyalinization-degeneration and increased chronic interstitial nephritis were also noted.

Blood, plasma, serum, body fat, and liver can be assayed for PHAs. These levels can be linked to exposure and clinical and pathologic findings to establish a putative diagnosis.

Treatment and Control: There is no known treatment for intoxication by PHAs. Supportive care is recommended. Attention should be given to the indoor environment, the use of nonplastic feeding and watering utensils, and feed sources to prevent exposures to PBDEs. Avoiding contact with materials impregnated with PBDEs reduces the percutaneous exposure of companion animals. Avoiding household furnishings and plastics that contain PBDEs generally reduces the levels of PBDEs in the indoor environment. Allowing a companion animal more access to the outdoors reduces the indoor exposure to PBDEs. The PHAs in body fat are excreted in milk fat and contribute to the body burden of the neonate. The levels in milk are higher in the first lactation.

INSECTICIDE AND ACARICIDE (ORGANIC) TOXICITY

Insecticides are any substance or a mixture of substances intended to prevent, destroy, repel, or mitigate insects. Similarly, acaricides are substances that can destroy mites. A chemical can exert both insecticidal and acaricidal effects. Based on their properties, these chemicals can be classified into four groups: 1) organophosphates, 2) carbamates, 3) organochlorines, and 4) pyrethroids and pyrethroids. Because of worldwide use, these chemicals pose health risks to nontarget species, including people, domestic and companion animals, wildlife, and aquatic species. In large animals,

poisoning is often due to inadvertent or accidental use, whereas in small animals (particularly dogs) poisoning is often due to malicious intent.

Pesticide labels must carry warnings against use on unapproved species or under untested circumstances. These warnings may pertain to acute or chronic toxicity, or to residues in meat, milk, or other animal products. Because labels change to meet current government regulations, it is important to always read and follow all label directions accompanying the product.

Each exposure, no matter how brief or small, results in some of the compound being absorbed and perhaps stored. Repeated short exposures may eventually result in intoxication because of cumulative effect. Every precaution should be taken to minimize human exposure. This may include frequent changes of clothing with bathing at each change, or if necessary, the use of respirators, rain gear, and gloves impervious to pesticides. Respirators must have filters approved for the type of insecticide being used (eg, ordinary dust filters will not protect the operator from organophosphorus insecticide fumes). Such measures are generally sufficient to guard against intoxication. Overexposure to chlorinated hydrocarbon insecticides is difficult to measure except by the occurrence of overt signs of poisoning.

Organophosphate and carbamate insecticides produce their toxicity by inactivation of acetylcholinesterase (AChE) enzyme at the synapses in nervous tissue and neuromuscular junctions, and in RBCs. Therefore, the cholinesterase-inhibiting property of organophosphates or carbamates may be used to indicate degree of exposure if the activity of the blood/RBC-AChE is determined during an early period of exposure.

Organic pesticides are known to exert deleterious effects on fish and wildlife as well as on domestic species. In no event should amounts greater than those specifically recommended be used, and maximal precautions should be taken to prevent drift or drainage to adjoining fields, pastures, ponds, streams, or other premises outside the treatment area.

The safety and exposure level of these compounds in target species has been carefully established, and application recommendations and regulations must be followed. Individuals, including veterinarians, have been prosecuted for failure to follow label directions or to heed label warnings and for failure to warn animal owners of the necessary precautions.

An ideal insecticide or acaricide should be efficacious without risk to livestock or persons making the application and without leaving residues in tissues, eggs, or milk. Only a few compounds may meet all these requirements.

Poisoning by organic insecticides and acaricides may be caused by direct application, by ingestion of contaminated feed or forage treated for control of plant parasites, or by accidental exposure. This discussion is limited to only those insecticides or acaricides most frequently hazardous to livestock or likely to leave residues in animal products.

Chemical synthesis rarely yields 100% of the product of interest, and normally there are, in variable proportions, structurally related compounds that have biologic effects different from those of the compound sought. A prime example is dichlorodiphenylethane (DDD): the *p,p'*-isomer is an effective insecticide of low toxicity for most mammals; the *o,p'*-isomer causes necrosis of the adrenal glands of people and dogs and is used to treat certain adrenal malfunctions.

In general, products stored under temperature extremes or held in partially emptied containers for long periods may deteriorate. But during storage, malathion produces isomalathion, which is many times more toxic than malathion. In addition to isomalathion, two other technical impurities of malathion (malaoxon and trimethyl phosphorodithioate) can be formed and can potentiate the toxicity of malathion by several fold. Similar impurities can be formed and potentiate the toxicity of another organophosphate insecticide, phenthoate. Storing a chemical in anything but the original container is hazardous, because in time its identity may be forgotten. Accidental contact with animals or people may then have disastrous consequences. Consumer-mixed and unapproved combinations can be very dangerous and should never be used. For example, simultaneous administration of two organophosphate insecticides can result in potentiation of malathion toxicity by a hundredfold.

A number of cholinesterase-inhibiting, carbamate and organophosphate insecticides (eg, carbaryl, dichlorvos, methiocarb, carbofuran, paraoxon, mevinphos, aldicarb, and monocrotophos) are also immunotoxic. Impaired macrophage signaling through interleukins 1 and 2 appears to be involved, and the insecticide levels that cause this effect are very low. This can lead to subtle but damaging influences on the health of exposed animals.

CARBAMATE INSECTICIDES

The carbamates are esters of carbamic acid. Unlike organophosphates, carbamates are not structurally complex. Presently, the volume of carbamates used exceeds that of organophosphates, because carbamates are considered to be safer than organophosphates.

Aldicarb: The oral LD₅₀ in rats is 0.9 mg/kg, and the dermal LD₅₀ in rabbits is 5 mg/kg. Dogs are frequently poisoned with malicious intent.

Carbaryl: The oral LD₅₀ in rats is 307 mg/kg, and the dermal LD₅₀ in rabbits

is 2,000 mg/kg. A 2% spray is nontoxic to calves; 4% is nontoxic to mature cattle when applied dermally.

Carbofuran: The oral LD₅₀ in rats, dogs, chickens, ducks, pheasants, quails, and wild birds is 8, 19, 6.3, 0.415, 4.2, 5, and 0.42 mg/kg, respectively. Dogs are commonly poisoned with malicious intent by tainting food. The minimum toxic dose in cattle and sheep is 4.5 mg/kg, becoming lethal at 18 and 9 mg/kg, respectively. Cattle and other domestic animals are often poisoned by accidental exposure. Pigs have been poisoned after drinking water contaminated by this compound. In Africa, wildlife populations (including deer, lions, and birds) are declining because of malicious use of carbofuran. The dermal LD₅₀ in rabbits is 2,550 mg/kg.

Methomyl: The oral LD₅₀ in rats is 17 mg/kg, and the dermal LD₅₀ in rabbits is >2,000 mg/kg. Dogs have been commonly poisoned with malicious intent by tainting food. Cattle have been reported to be poisoned after consumption of forage inadvertently sprayed with methomyl.

Propoxur: The oral LD₅₀ is 95 mg/kg in rats and >800 mg/kg in goats. The dermal LD₅₀ in rabbits is >1,000 mg/kg.

Clinical Findings: The carbamate insecticides act similarly to the organophosphates (see p 3064) in that they inhibit acetylcholinesterase (AChE) at nerve synapses and neuromuscular junctions. This inhibition is reversible because the inhibiting bond is much less durable; thus, the inhibition of blood AChE frequently is not evident at the laboratory. Signs include hypersalivation, GI hypermotility, abdominal cramping, vomiting, diarrhea, sweating, dyspnea, cyanosis, miosis, muscle fasciculations (in extreme cases, tetany followed by weakness and paralysis), and convulsions. In brief, the acronym SLUD (salivation, lacrimation, urination, and diarrhea) describes the overall clinical features of carbamate poisoning. Death usually results from respiratory failure and hypoxia due to bronchoconstriction leading to tracheobronchial secretion and pulmonary edema.

Diagnosis: Diagnosis of carbamate poisoning usually depends on history of exposure to a particular carbamate and response to atropine therapy. However, when a history of carbamate poisoning is not provided, but cholinergic signs and a clear positive response to atropine suggest carbamate or organophosphate poisoning, AChE activity levels should be determined

in RBCs or whole blood (live animals), or in brain cortex (dead animals). Enzyme activity that is significantly inhibited (>50%) is confirmatory. Signs of hypercholinergic activity are usually seen with AChE inhibition >70%. Screening GI contents for carbamate insecticides by gas chromatography coupled with mass spectrometry is helpful in identification, confirmation, and quantitation of a particular carbamate and aids in differential diagnosis if an organophosphate insecticide is also involved.

Treatment: Treatment of carbamate poisoning is similar to that of organophosphate poisoning in that atropine sulfate injections readily reverse the effects. Recommended dosages for atropine are as follows: dogs and cats—dosed to effect (repeated as needed), usually 0.2–2 mg/kg, parenterally, one-fourth of the dose given IV and the remainder given SC (cats should be dosed at the lower end of the range); cattle and sheep—0.6–1 mg/kg, one-fourth of the dose IV and the remainder SC, repeated as needed; horses and pigs—0.1–0.2 mg/kg, IV, repeated as needed.

Pralidoxime (2-PAM) should not be used to treat carbamate poisoning. 2-PAM can be beneficial if poisoning is caused by a mixture of organophosphates and carbamates. Signs of excessive cholinergic activity may warrant its use, in case the cause is organophosphate exposure. 2-PAM can be fatal if given too rapidly; it must be administered slowly (ie, in 5% saline over a 10-min period). See also ORGANOPHOSPHATES, p 3064. Also, 2-PAM solution should be prepared freshly, because old solutions are known to produce cyanide. Use of morphine or barbiturates is contraindicated.

CHLORINATED HYDROCARBON COMPOUNDS

Because of persistent tissue residues and chronic toxicity, use of chlorinated hydrocarbon compounds has been drastically curtailed. Only lindane and methoxychlor are approved for use on or around livestock. Detectable residues of some chlorinated hydrocarbon insecticides, including BHC, heptachlor, heptachlor epoxide, lindane, and oxychlordane, can be found in fatty tissue after acute or chronic exposure.

Aldrin: Aldrin is a potent insecticide similar to dieldrin with the same order of toxicity (see below). It is no longer registered in the USA but was used for termite control. The oral LD₅₀ in rats is 39 mg/kg, and the dermal LD₅₀ in rabbits is 65 mg/kg. In farm animals, the toxic dose is ~15–30 mg/kg.

Benzene Hexachloride (BHC, HCH, Hexachlorocyclohexane): Benzene hexachloride (BHC) is composed of 12%–45% γ isomer. BHC was a useful insecticide for large animals and dogs but is highly toxic to cats in the concentrations necessary for parasite control. Only the γ isomer (γ -BHC, lindane) is a useful insecticidal agent; the other isomers are stored for excessively long periods in body tissues. Lindane, which contains >99% of the γ isomer, should be used in preference to the technical grade of BHC, which contains several isomers. The oral LD₅₀ of lindane in rats is 76 mg/kg, and the dermal LD₅₀ in rabbits is 500 mg/kg. Presently, BHC is not sold in the USA.

Cattle in good condition have tolerated 0.2% lindane applications, but stressed, emaciated cattle have been poisoned from spraying or dipping in 0.075% lindane. Horses and pigs appear to tolerate 0.2%–0.5%, and sheep and goats ordinarily tolerate 0.5% applications. Emaciation and lactation increase the susceptibility of animals to poisoning by lindane; such animals should be treated with extreme caution. Young calves are very susceptible to lindane and are poisoned by a single oral dose of 4.4 mg/kg. Mild signs appear in sheep given 22 mg/kg, and death occurs at 100 mg/kg. Adult cattle have tolerated 13 mg/kg without signs. BHC is stored in body fat and excreted in milk.

Chlordane: Chlordane is no longer registered as an insecticide in the USA. Exposure occurs when livestock consume treated plants or when they come in direct contact through carelessness and accidents. The lethal dose of chlordane for most species is in the range of 200–300 mg/kg. Very young calves have been killed by doses of 44 mg/kg, and the minimum toxic dose for cattle is ~88 mg/kg. Cattle fed chlordane at 25 ppm of their diet for 56 days showed 19 ppm in their fat at the end of the feeding. Topical emulsions and suspensions have been used safely on dogs at concentrations up to 0.25%, provided freshly diluted materials were used; dry powders up to 5% have been safe. The no-effect level in dogs in a 2-yr feeding study was 3 mg/kg. Pigeons and Leghorn cockerels and pullets suffered no effects after 1–2 mo exposure to vapors emanating from chlordane-treated surfaces. The oral LD₅₀ in rats is 283 mg/kg, and the dermal LD₅₀ in rabbits is 580 mg/kg.

Dieldrin: Dieldrin is not a registered pesticide in the USA. Residues limit its application, and it is one of the most toxic chlorinated hydrocarbon insecticides. The oral LD₅₀ in rats is 40 mg/kg, and the dermal LD₅₀ in rabbits is 65 mg/kg. Young dairy calves are poisoned by 8.8 mg/kg, PO, but tolerate

4.4 mg/kg, whereas adult cattle tolerate 8.8 mg/kg and are poisoned by 22 mg/kg. Pigs tolerate 22 mg/kg and are poisoned by 44 mg/kg. Horses are poisoned by 22 mg/kg. Because of its effectiveness against insect pests on crops and pasture and the low dosage per acre, dieldrin is not likely to poison livestock grazing the treated areas. Diets containing 25 ppm of dieldrin have been fed to cattle and sheep for 16 wk without harmful effects other than residues in fat, which are slow to disappear. Great care must be exercised in marketing animals that have grazed treated areas or consumed products from previously treated areas. There is a zero tolerance level for residues in edible tissues.

Statements pertaining to dieldrin also apply, in general, to **endrin**, the most toxic of the three chlorinated cyclodiene insecticides.

Endosulfan: Endosulfan is widely used to control insect and mite pests on a variety of crops and orchards. It is heavily used on tobacco. Endosulfan is very toxic to mammalian species. The oral LD₅₀ in rats is 18 mg/kg, and the dermal LD₅₀ in rabbits is 74 mg/kg. The LD₅₀ of endosulfan in dogs is 77 mg/kg. Its lethal dose in cattle is 8 g. Generally, cattle are poisoned by accidental exposure, and dogs are poisoned by malicious intent. Exposure of cattle to endosulfan produces residues in the liver, kidneys, muscle, and milk.

Heptachlor: Heptachlor is not currently registered in the USA and is not recommended for use on livestock in the USA. Among its few agricultural applications, heptachlor is used for residual control of subterranean termites. The oral LD₅₀ in rats is 40 mg/kg, and the dermal LD₅₀ in rabbits is 119 mg/kg. Because it is very effective against certain plant-feeding insects, it is encountered from time to time in some geographic areas grazed by livestock. Young dairy calves tolerate dosages as high as 13 mg/kg but are poisoned by 22 mg/kg. Sheep tolerate 22 mg/kg but are poisoned by 40 mg/kg. Diets containing 60 ppm of heptachlor have been fed to cattle for 16 wk without harmful effects other than residues in fat. Heptachlor is converted to heptachlor epoxide by animals and stored in body fat. For this reason, a specific analysis performed for heptachlor usually yields negative results, while that for epoxide is positive.

Methoxychlor: Methoxychlor is one of the safest chlorinated hydrocarbon insecticides and one of the few with active registration in the USA. The oral LD₅₀ in rats is 5,000 mg/kg, and the dermal LD₅₀ in rabbits is 2,820 mg/kg. Young dairy calves

tolerate 265 mg/kg; 500 mg/kg is mildly toxic. While 1 g/kg produces rather severe poisoning in young calves, sheep are not affected. One dog was given 990 mg/kg/day for 30 days without showing signs. Six applications to cattle of a 0.5% spray at 3-wk intervals produced fat residues of 2.4 ppm; ~0.4 ppm of methoxychlor is found in milk 1 day after spraying a cow with a 0.5% concentration. Methoxychlor sprays are not approved for use on animals producing milk for human consumption. Cattle and sheep store essentially no methoxychlor when fed 25 ppm in the total diet for 112 days. If methoxychlor is used as recommended, the established tolerance in fat will not be exceeded. Commercial products are available for garden, orchard, and field crops, and for horses and ponies.

Numerous reports suggest that methoxychlor has negative reproductive effects in laboratory animal experiments, but this has not been seen in the field.

Toxaphene: Toxaphene is no longer under active registration in the USA. It has been used with reasonable safety if recommendations were followed, but it can cause poisoning when applied or ingested in excessive quantities. The oral LD_{50} in rats is 40 mg/kg, and the dermal LD_{50} in rabbits is 600 mg/kg. Dogs and cats are particularly susceptible. Young calves have been poisoned by 1% toxaphene sprays, while all other farm animals except poultry can withstand 1% or more as sprays or dips. Chickens have been poisoned by dipping in 0.1% emulsions, and turkeys have been poisoned by spraying with 0.5% material. Toxaphene is primarily an acute toxicant and does not persist long in the tissues. Adult cattle have been mildly intoxicated by 4% sprays and severely affected by 8%. Adult cattle have been poisoned from being dipped in emulsions that contained only 0.5% toxaphene (an amount ordinarily safe) because the emulsions had begun to break down, allowing the fine droplets to coalesce into larger droplets that readily adhere to the hair of cattle. The resultant dosage becomes equivalent to that obtained by spray treatments of much higher concentrations. Toxaphene is lethal to young calves at 8.8 mg/kg but not at 4.4 mg/kg. The minimum toxic dose for cattle is ~33 mg/kg, and for sheep between 22 and 33 mg/kg. Spraying Hereford cattle 12 times at 2-wk intervals with 0.5% toxaphene produced a maximum residue of 8 ppm in fat. Cattle fed 10 ppm of toxaphene in the diet for 30 days had no detectable toxaphene tissue residues, whereas steers fed 100 ppm for 112 days stored only 40 ppm in their fat (this

amount was eliminated 2 mo after the toxaphene was discontinued).

Clinical Findings: The chlorinated hydrocarbon insecticides are general CNS stimulants. They produce a great variety of signs—the most obvious are neuromuscular tremors and convulsions—and there may be obvious behavioral changes common to other poisonings and CNS infections. Body temperature may be very high. Affected animals are generally first noted to be more alert or apprehensive. Muscle fasciculation occurs, becoming visible in the facial region and extending backward until the whole body is involved. Large doses of DDT, DDD, endosulfan, lindane, and methoxychlor cause progressive involvement leading to trembling or shivering, followed by convulsions and death. With the other chlorinated hydrocarbons, muscular twitching is followed by convulsions, usually without the intermediate trembling. Convulsions may be clonic or tonic lasting from a few minutes to several hours, or intermittent and leading to the animal becoming comatose. High fever may accompany convulsions, particularly in warm environments.

Behavioral changes such as abnormal postures (eg, resting the sternum on the ground while remaining upright in the rear, keeping the head down between the forelegs, "head pressing" against a wall or fence, or continual chewing movements) may be seen. Occasionally, an affected animal becomes belligerent and attacks other animals, people, or moving objects. Vocalization is common. Some animals are depressed, almost oblivious to their surroundings, and do not eat or drink; they may last longer than those showing more violent symptoms. Usually, there is a copious flow of thick saliva and urinary incontinence. In certain cases, the clinical signs alternate, with the animal first being extremely excited, then severely depressed.

The severity of the signs seen at a given time is not a sure prognostic index. Some animals have only a single convulsion and die, whereas others suffer innumerable convulsions but subsequently recover. Animals showing acute excitability often have a fever $>106^{\circ}\text{F}$ (41°C). The signs of poisoning by these insecticides are highly suggestive but not diagnostic; other poisons and encephalitis or meningitis must be considered.

Signs of acute intoxication by chlordane in birds are nervous chirping, excitability, collapse on hocks or side, and mucous exudates in the nasal passages. Signs of subacute

and chronic intoxication are molting, dehydration and cyanosis of the comb, weight loss, and cessation of egg production.

Lesions: If death has occurred suddenly, there may be nothing more than cyanosis. More definite lesions occur as the duration of intoxication increases. Usually, there is congestion of various organs (particularly the lungs, liver, and kidneys) and a blanched appearance of all organs if the body temperature was high before death. The heart generally stops in systole, and there may be many hemorrhages of varying size on the epicardium. The appearance of the heart and lungs may suggest a peracute pneumonia and, if the animal was affected for more than a few hours, there may be pulmonary edema. The trachea and bronchi may contain a blood-tinged froth. In many cases, the CSF volume is excessive, and the brain and spinal cord frequently are congested and edematous.

Diagnosis: Chemical analysis of brain, liver, kidney, fat, and stomach or rumen contents is necessary to confirm chlorinated hydrocarbon compound poisoning. The suspected source, if identified, should also be analyzed. Brain levels of the insecticide are the most useful. Whole blood, serum, and urine from live animals may be analyzed to evaluate exposure in the rest of the herd or flock. In food animal poisoning, if exposure is more than just the animals visibly affected, fat biopsies from survivors may be necessary to estimate the potential residue. Identification, confirmation, and quantitation of organochlorine insecticides are usually done by gas chromatography coupled with mass spectrometry.

Treatment: There are no known specific antidotes to chlorinated hydrocarbon compound poisoning. When exposure is by spraying, dipping, or dusting, a thorough bathing without irritating the skin (no brushes), using detergents and copious quantities of cool water, is recommended. If exposure is by ingestion, gastric lavage and saline purgatives are indicated. The use of digestible oils such as corn oil is contraindicated; however, heavy-grade mineral oil plus a purgative hastens the removal of the chemical from the intestine. Activated charcoal appears to be useful in preventing absorption from the GI tract. When signs are excitatory, a sedative anticonvulsant such as a barbiturate or diazepam is indicated. Anything in the environment that stresses the animal (eg, noise, handling) should be reduced or removed if possible. If the animal shows marked depression, anorexia, and

dehydration, therapy should be directed toward rehydration and nourishment either IV or by stomach tube. Residues in exposed animals may be reduced by giving a slurry of activated charcoal or providing charcoal in feed. Feeding phenobarbital, 5 g/day, may hasten residue removal.

INSECTICIDES DERIVED FROM PLANTS

Most insecticides derived from plants (eg, rotenone from *Derris* and pyrethrins from *Chrysanthemum* or *Pyrethrum*) have traditionally been considered safe for use on animals. **Nicotine** in the form of nicotine sulfate is an exception. Unless it is carefully used, poisoning may result. Pets are exposed to tobacco by ingesting commercial tobacco products (eg, cigarettes or chewing tobacco), whereas livestock may consume discarded tobacco stalks or hay contaminated with tobacco plant drippings in the barn. The minimum lethal dose of nicotine is 1 g in cattle, 0.2–0.3 g in horses, 0.1–0.2 g in sheep, and 0.02–0.1 g in dogs and cats. Affected animals show tremors, incoordination, nausea, disturbed respiration, muscle paralysis, and finally coma and death. Nicotine and related alkaloids from tobacco can cross the placenta and produce teratogenic effects. Recovery from sublethal doses is usually complete within 3 hr. Death occurs within a matter of hours from paralysis of thoracic respiratory muscles and cardiac arrest. Necropsy may reveal parts of tobacco leaves or stalks in the rumen contents. Lesions include pale mucous membranes, dark blood, hemorrhages on the heart and in the lungs, and congestion of the brain. Treatment consists of removing the material by washing or by gastric lavage with tannic acid, administering activated charcoal, providing artificial respiration, and treating for cardiac arrest and shock.

Pyrethrins: Pyrethrins are insecticides obtained from the flowers of *C. cinerariaefolium* and have been used as insecticides for many years. Pyrethrins and pyrethroids produce toxicity affecting primarily the sodium channel, but also chloride and calcium channels of nerve cells. These insecticides also interact with nicotinic acetylcholine receptors. Synergists, such as piperonyl butoxide, sesamex, piperonyl cyclonene, etc, are added to increase stability and effectiveness. This is accomplished by inhibiting mixed function oxidases, enzymes that detoxify pyrethrins and pyrethroids; unfortunately, this also potentiates mammalian toxicity.

Pyrethroids: Pyrethroids are synthetic derivatives of natural pyrethrins. There are two types of pyrethroids. Type I compounds that lack an α -cyano substituent include pyrethrin I, allethrin, tetramethrin, kadethrin, resmethrin, phenothrin, and permethrin. Type II compounds that contain a stabilizing α -cyano-3-phenoxybenzyl component include cyfluthrin, cypermethrin, fenpropanthrin, deltamethrin, cyphenothrin, fenvalerate, and fluralinate. Type I pyrethroids produce a neurologic syndrome through their effects on both the central and peripheral nervous systems, with signs including tremors, incoordination, prostration, seizures, and death. Type II pyrethroids work primarily by CNS mechanisms to exert the choreoathetosis/salivation syndrome, characterized by hyperactivity, hunched back, salivation, tremors, and incoordination progressing to sinuous writhing movements.

Diagnosis of pyrethrin/pyrethroid poisoning is based on clinical signs, history of exposure, and determination of insecticide residue in body tissues and fluids. These insecticides do not produce characteristic pathologic lesions.

Generally, symptomatic and supportive treatment is required after ingestion of a dilute pyrethrin or pyrethroid preparation. Toxicity may also be due to the solvent. Induction of emesis may be contraindicated. A slurry of activated charcoal at 2–8 g/kg may be administered, followed by a saline cathartic (magnesium or sodium sulfate [10% solution] at 0.5 mg/kg). Vegetable oils and fats, which promote the intestinal absorption of pyrethrum, should be avoided. If dermal exposure occurs, the animal should be bathed with a mild detergent and cool water. The area should be washed very gently so as not to stimulate the circulation and enhance skin absorption. Initial assessment of the animal's respiratory and cardiovascular integrity is important. Further treatment involves continuing symptomatic and supportive care. Seizures should be controlled with either diazepam (administered to effect at 0.2–2 mg/kg, IV) or methocarbamol (55–220 mg/kg, IV, not exceeding 200 mg/min). Phenobarbital or pentobarbital (IV), to effect, can be used if diazepam or methocarbamol are too short-acting.

D-Limonene: D-Limonene is the major component of the oil extracted from citrus rind. It is used for the control of fleas on cats and for other insect pests. Adult fleas and eggs appear to be most sensitive to D-limonene, which is more effective if combined with the synergist piperonyl butoxide. At recommended dosages, the solution containing D-limonene appears to be safe, but

increasing the concentration 5–10 fold in sprays or dips increases the severity of toxic signs, which include hypersalivation, muscle tremors, ataxia, and mild to severe hypothermia. The inclusion of piperonyl butoxide in the formulation potentiates the toxicity in cats. Allergies have also been reported in people in contact with D-limonene, and it appears to increase dermal absorption of some chemicals. When orally administered to dogs, D-limonene causes vomiting (median effective dose 1.6 mL/kg). No antidote is available.

ORGANOPHOSPHATES

The organophosphates (OPs) are derivatives of phosphoric or phosphonic acid. OPs have replaced the banned organochlorine compounds and are a major cause of animal poisoning. They vary greatly in toxicity, residue levels, and excretion. Many have been developed for plant and animal protection, and in general, they offer a distinct advantage by producing little tissue and environmental residue. Some of the OPs developed initially as pesticides are also used as anthelmintics. Five such compounds include dichlorvos, trichlorfon, haloxon, naphthalophos, and crufomate. The first two are primarily used against parasitic infestations in horses, dogs, and pigs; the latter three are used against parasites in ruminants.

Many of the OPs now used as pesticides (eg, chlorpyrifos, diazinon, fenitrothion, malathion, parathion, etc) are not potent inhibitors of cholinesterase until activated in the liver by microsomal oxidation enzymes; they are generally less toxic, and intoxication occurs more slowly. Certain OP preparations are microencapsulated, and the active compound is released slowly; this increases the duration of activity and reduces toxicity, but the toxic properties are still present.

Organophosphate Insecticides

Azinphos-methyl (or -ethyl): The maximum nontoxic oral dose is 0.44 mg/kg for calves, 2.2 mg/kg for cattle and goats, and 4.8 mg/kg for sheep. The oral LD₅₀ in rats is 5 mg/kg, and the dermal LD₅₀ in rabbits is 220 mg/kg.

Carbophenothion: Carbophenothion has been used as a spray for fruit trees and as a dip or spray for sheep blowfly, keds, and lice. Dairy calves <2 wk old sprayed with water-based formulations showed poisoning at concentrations $\geq 0.05\%$, and adult cattle were poisoned by spraying with 1%. Sheep and goats have been poisoned by 22 mg/kg, PO, but not by 8 mg/kg. In sheep, 0.1% as a dip produces no signs of poison-

ing. The LD_{50} for rats is ~31 mg/kg; a daily dosage of 2.2 mg/kg for 90 days produced poisoning. Dogs tolerated a diet containing 32 ppm for 90 days. A single application of a powder containing 1% of carbophenothion is lethal to cats.

Chlorfenvinphos: Adult cattle were poisoned by 5% or higher sprays, whereas young calves were poisoned at concentrations of 2%. The minimum oral toxic dose appears to be ~22 mg/kg for cattle of all ages. The acute oral LD_{50} for rats is 12 mg/kg, and the dermal LD_{50} in rabbits is 3,200 mg/kg.

Chlorpyrifos: The oral LD_{50} is 500 mg/kg in goats and 941 mg/kg in rats. In comparison with calves, steers, and cows, bulls (particularly of the exotic breeds) are highly susceptible to a single dose of chlorpyrifos. The maximum tolerated dose of chlorpyrifos in sheep is 750 mg/kg. Sheep given 850 mg/kg died 5 days after dosing, those given 900 mg/kg died on the third day, and a dose of 1,000 mg/kg was lethal within 30 hours. Onset of poisoning signs is usually delayed compared with that of many other commonly used organophosphates because of the conversion of chlorpyrifos to the active cholinesterase inhibitor chlorpyrifos-oxon. Chlorpyrifos produces reproductive and developmental toxicity.

Coumaphos: Coumaphos is used against cattle grubs and a number of other ectoparasites and for treatment of premises. The maximum concentration that may be safely used on adult cattle, horses, and pigs is 0.5%. Young calves and all ages of sheep and goats must not be sprayed with concentrations >0.25%; 0.5% concentrations may be lethal. Adult cattle may show mild toxicity at 1% concentrations. The minimum lethal dose for calves appears to be between 10 and 40 mg/kg. A dose of 25 mg/kg is usually fatal in sheep. The oral LD_{50} in rats is 13 mg/kg.

Crotoxyphos: Crotoxyphos is used as a spray or powder for the control of ectoparasites on cattle and pigs. Crotoxyphos is of rather low toxicity; however, Brahman cattle are markedly more susceptible than European breeds. Cattle (except as above), sheep, goats, and pigs all tolerate sprays containing crotoxyphos at 0.5% levels or higher. Crotoxyphos is safe at a level of 1%, although skin lesions have been found in pigs. Toxic doses appears to be in the 2% range, except for in Brahman cattle, in which 0.144%–0.3% may be toxic.

Demeton: Demeton is used as a systemic insecticide against sucking insects and mites. Demeton is used mainly as a foliage spray and has a relatively long residual life. It is a mixture of demeton-O and demeton-S and is

highly toxic to mammals. The oral LD_{50} is 8 mg/kg in goats and 2 mg/kg in rats; the dermal LD_{50} in rats and rabbits is 8 mg/kg. Demeton-O poisoning developed in several hundred cattle grazing near cotton treated with this insecticide. The corresponding analogues of demeton (demeton-O-methyl and demeton-S-methyl) are also used for similar purposes but are less toxic than demeton.

Diazinon: Young calves appear to tolerate 0.05% spray but are poisoned by 0.1% concentrations. Adult cattle may be sprayed at weekly intervals with 0.1% concentrations without inducing poisoning. Young calves tolerate 0.44 mg/kg, PO, but are poisoned by 0.88 mg/kg. Cattle tolerate 8.8 mg/kg, PO, but are poisoned by 22 mg/kg. Sheep tolerate 17.6 mg/kg but are poisoned by 26 mg/kg. The oral LD_{50} in rats is 300 mg/kg, and the dermal LD_{50} in rabbits is 379 mg/kg.

Dichlorvos: Dichlorvos has many uses on both plants and animals. It is rapidly metabolized and excreted, and residues in meat and milk are not a problem if label directions are followed. It is of moderate toxicity, with a minimum toxic dose of 10 mg/kg in young calves and 25 mg/kg in horses and sheep. The oral LD_{50} in rats is 25 mg/kg, PO, and the dermal LD_{50} in rabbits is 59 mg/kg. A 1% dust was not toxic to cattle. Flea collars containing dichlorvos may cause skin reactions in some pets. Cats wearing dichlorvos-impregnated collars can develop signs of ataxia-depression syndrome, followed by death.

Dimethoate: Dimethoate is used extensively in horticulture as a systemic insecticide, but it also kills insects by contact. When administered PO, the minimum toxic dose for young dairy calves was ~48 mg/kg, while 22 mg/kg was lethal for cattle 1 yr old. Daily doses of 10 mg/kg for 5 days in adult cattle lowered blood cholinesterase activity to 20% of normal but did not produce poisoning. Horses have been poisoned by doses of 60–80 mg/kg, PO. When applied topically, 1% sprays have been tolerated by calves, cattle, and adult sheep. The oral LD_{50} in rats is 215 mg/kg, and the dermal LD_{50} in rabbits is 400 mg/kg.

Dioxathion: Dioxathion is a nonsystemic acaricide and insecticide for the control of ticks. Dioxathion is a mixture of cis- and trans-isomers, usually in the ratio of 1:2. The cis-isomer is more toxic than the trans-isomer. Used on both plants and animals, it is rapidly metabolized and not likely to produce residues in meat greater than the 1 ppm official tolerance. Concentrations of ≥0.15% are generally used on animals. The minimum toxic dose in calves is 5 mg/kg. Sprays of 0.5%

in cattle and sheep or 0.25% in goats and pigs are nontoxic. Sprays at concentrations up to 0.1% are usually safe for calves and lambs. Twice this concentration may produce signs of poisoning. Dioxathion at 8.8 mg/kg, PO, has killed young calves, and it produced intoxication at 4.4 mg/kg. Emaciated cattle with severe tick infestation are more frequently poisoned than healthy animals. Maximum residues of dioxathion in adipose tissue of cattle occur 2–4 days after dipping. The elimination half-life, after obtaining maximum concentrations, is ~16 days.

Disulfoton: The maximum nontoxic oral dose is 0.88 mg/kg for young calves, 2.2 mg/kg for cattle and goats, and 4.8 mg/kg for sheep. Poisoning has occurred in cattle after consuming harvested forages previously sprayed with this insecticide. The oral LD₅₀ in rats is 2 mg/kg, and the dermal LD₅₀ in rabbits is 6 mg/kg. Chronic exposure to disulfoton may result in tolerance to toxicity.

Ethyl 4-Nitrophenyl Phenylphosphonothioate (EPN): EPN is a nonsystemic insecticide and acaricide structurally related to parathion. The acute oral LD₅₀ in rats is 8–36 mg/kg. EPN at a dosage of 10 mg/kg was found to be nontoxic to adult cattle and sheep. The minimum oral toxic dose of EPN is 2.5 mg/kg in calves and 25 mg/kg in sheep and yearling cattle. Sprays containing 0.025%–0.05% EPN are toxic to young calves, and 0.25% EPN is lethal. Dogs were not poisoned at dosages >100 mg/kg.

Famphur: The oral LD₅₀ in rats is 35 mg/kg, and the dermal LD₅₀ in rabbits is 2,730 mg/kg. The maximum nontoxic dose is 10 mg/kg in calves and 50 mg/kg in cattle, sheep, and horses. In general, Brahman cattle are especially susceptible to famphur toxicity. This compound is effective against warbles in cattle, but (as for all grubicides) directions must be followed as to time of application; larvae killed while migrating and the resultant local reaction can cause serious problems. In several instances, famphur poisoning occurred in birds (mainly magpies and robins) shortly after cattle had been treated with a pouron preparation containing famphur.

Fenitrothion: Fenitrothion, also known as sunithion, is used as a contact insecticide in agriculture and horticulture. The oral LD₅₀ in rats is 250 mg/kg, and the dermal LD₅₀ in rabbits is 1,300 mg/kg. When applied to cattle, its metabolites are excreted at low levels in milk and urine. Fenitrothion produces reproductive and developmental toxicity in chickens.

Fenthion: Fenthion is commonly applied topically to control warble infestation in

cattle and fleas in dogs. The minimum toxic dose, PO, is 25 mg/kg for cattle; 50 mg/kg is lethal to sheep. The oral LD₅₀ in rats is 255 mg/kg, and the dermal LD₅₀ in rabbits is 330 mg/kg.

Malathion: Malathion is one of the safest organophosphates because of its selective toxicity; it is highly toxic to insects but much less toxic to mammalian species. The oral LD₅₀ in rats is 885 mg/kg, and the dermal LD₅₀ in rabbits is 4,000 mg/kg. The oral acute toxic dose in calves is 10–20 mg/kg and in adult cattle and sheep is 50–100 mg/kg. In a chronic study in buffalo calves (6–9 mo old), daily oral administration of malathion at 0.5 mg/kg for 1 yr produced no biochemical or clinical effects. Dosages >1 mg/kg inhibited blood acetylcholinesterase (AChE) activity and increased liver enzymes (ALT and AST). A 20 mg/kg dose produced clinical signs after 10 days. The acute oral LD₅₀ in buffalo calves is 53 mg/kg. Dermal application by spray containing 0.5% or 1% of malathion had no apparent effect on calves, but 5% spray caused death within 75 hr. Malathion at 0.5% or 1% should not be sprayed on calves for more than 3 consecutive days. Malathion is excreted in cow's milk.

Methyl Parathion: Methylparathion is less toxic than parathion (diethylparathion). The LD₅₀ in rats from a single oral dose is 9–25 mg/kg, and the dermal LD₅₀ in rabbits is 63 mg/kg. Methyl parathion at 2.5 mg/kg had no ill effect, but 10 mg/kg daily quickly led to toxic signs. The lethal dose in cattle is 100 mg/kg. Methyl parathion is excreted in cow's milk. Methyl parathion produces reproductive and developmental toxicity.

Mevinphos: The LD₅₀ in rats is 3 mg/kg, and the dermal LD₅₀ in rabbits is 16 mg/kg. Mevinphos has been commonly used to control the population of birds, and thereby caused poisoning in nontarget species. Mevinphos at 200 ppm in the diet is lethal in dogs.

Naled: Naled is essentially a dibrominated dichloro, which has the ability to act as a contact insecticide. It has a broad spectrum of insecticidal action. Because it has a short residual life, it poses relatively little hazard to fish and wildlife. The oral LD₅₀ in rats is 191 mg/kg, and the dermal LD₅₀ in rabbits is 390 mg/kg.

Oxydemeton-methyl: The maximum nontoxic oral dose is 0.88 mg/kg for young calves, 2.2 mg/kg for cattle, and 4.8 mg/kg for sheep and goats.

Parathion: Parathion (diethyl parathion) is widely used for control of plant pests and is approximately one-half as toxic as tetraethyl pyrophosphate (*see below*). The

oral LD₅₀ in rats is 3 mg/kg, and the dermal LD₅₀ in rabbits is 6.8 mg/kg. It is used as a dip and spray for cattle in some countries (not in the USA). Most cases of occupational insecticide poisonings in people have been attributed to parathion or its degradation products. The minimum toxic dose in calves is 0.25–0.5 mg/kg and in cattle is 25–50 mg/kg. The minimum oral lethal dose in sheep is 20 mg/kg and in goats is 50 mg/kg. The LD₅₀ in dogs is 23–35 mg/kg and in cats is 15 mg/kg. Dermal sprays containing 0.02%, 1%, and 1% of parathion are lethal to calves, sheep, and goats, respectively. Parathion is used extensively to control mosquitoes and insects in orchards and on market garden crops. Normally, because so little is used per acre, it presents no hazard to livestock. However, because of the potency of parathion, care should be taken to prevent accidental exposure. Parathion does not produce significant residues in animal tissues.

Phorate: Phorate is closely related to demeton (see above). It is a systemic insecticide and miticide. The oral LD₅₀ in rats is 1.6 mg/kg, and the dermal LD₅₀ in rabbits is 2.5 mg/kg. The minimum toxic dose PO is 0.25 mg/kg in calves, 0.75 mg/kg in sheep, and 1 mg/kg in cattle.

Phosmet: Phosmet is a nonsystemic acaricide and insecticide. The minimum oral toxic dose is 25 mg/kg in cattle and calves and 50 mg/kg in sheep. Spraying with a 0.5% solution has no toxic effect, but a 1% solution of phosmet produces intoxication in cattle. Phosmet is not excreted in milk.

Ronnel (Fenchlorphos): Ronnel is an excellent oral systemic insecticide. It is effective against many ecto- and endoparasitic arthropods, including cattle grubs, screw worms, and sucking lice. Ronnel is also used as a residual spray insecticide to control flies, fleas, and cockroaches. The oral LD₅₀ in rats is 1,250 mg/kg, and the dermal LD₅₀ in rabbits is 2,000 mg/kg. Ronnel produces mild signs of poisoning in cattle at 132 mg/kg, but severe signs do not appear until the dosage is >400 mg/kg. The minimum toxic dose in sheep is 400 mg/kg. Concentrations as high as 2.5% in sprays have failed to produce poisoning of cattle, young dairy calves, or sheep. Poisoning usually occurs in two stages. The animal first becomes weak and, although able to move about normally, may be placid. Diarrhea, often flecked with blood, may also be seen. Salivation and dyspnea then appear if the dose was high enough. Blood cholinesterase activity declines slowly over 5–7 days. Ronnel produces residues in meat and milk; strict adherence to label restrictions is essential.

The residues may be removed by giving the animal activated charcoal for several days.

Ruelene: Ruelene is active both as a systemic and contact insecticide in livestock, has some anthelmintic activity, and has rather low toxicity. Dairy calves have been poisoned by 44 mg/kg, PO, while adult cattle require 88 mg/kg for the same effect. Sheep are moderately intoxicated by 176 mg/kg; Angora goats are about twice as sensitive. Pigs have been poisoned by 11 mg/kg and horses by 44 mg/kg. Most livestock tolerate a 2% topical spray.

Temephos: Temephos is used as an insecticide against mosquitoes and midges. It is of low toxicity to mammalian species. The oral LD₅₀ for rats is 1 g (or more)/kg, while the dermal LD₅₀ is >4 g/kg. Daily exposure of cattle for 1 yr at 1–1.5 mg/kg is known to produce clinical signs of poisoning and affect fertility in heifers.

Terbufos: This soil insecticide is used to control corn rootworms. The oral LD₅₀ in rats is 1.6 mg/kg. The minimum oral toxic dose is ~1.5 mg/kg for sheep and cattle. Cases of intoxication in cattle have occurred. Ingestion of 7.5 mg/kg was lethal to heifers.

Tetrachlorvinphos: Tetrachlorvinphos has low toxicity in dogs; chronic feeding studies indicate the lowest effect level was 50 mg/kg/day, and the no observed effect level (NOEL) was 3.13 mg/kg/day. The minimum toxic dose in pigs is 100 mg/kg.

Tetraethylpyrophosphate (TEPP): Tetraethyl pyrophosphate (TEPP) is one of the most acutely toxic insecticides. Although not used on animals, accidental exposure occurs occasionally. One herd of 29 cattle (including calves and adults) was accidentally sprayed with 0.33% TEPP emulsion; all died within 40 min.

Trichlorfon: Trichlorfon is used as a systemic insecticide and anthelmintic in domestic animals. It is also used as an acaricide in sheep at the dose rate of 80 mg/kg at weekly intervals for not more than 4 wk. The oral LD₅₀ in rats is 630 mg/kg, and the dermal LD₅₀ in rabbits is >2,000 mg/kg. As a spray, trichlorfon at a 1% concentration is tolerated by adult cattle; given PO, it is tolerated by young dairy calves at 4.4 mg/kg but produces poisoning at 8.8 mg/kg. Adult cattle, sheep, and horses appear to tolerate 44 mg/kg, while 88 mg/kg produces poisoning. Dogs were unaffected when fed 1,000 ppm of trichlorfon for 4 mo. Administration of trichlorfon at 75 mg/kg, PO, produces adverse clinical signs in dogs. Trichlorfon is metabolized rapidly.

Clinical Findings: In general, OP pesticides have a narrow margin of safety, and the dose-response curve is quite steep. Signs of OP poisoning are those of cholinergic overstimulation, which can be grouped into three categories: muscarinic, nicotinic, and central. Muscarinic signs, which are usually first to appear, include hypersalivation, miosis, frequent urination, diarrhea, vomiting, colic, and dyspnea due to increased bronchial secretions and bronchoconstriction. Nicotinic effects include muscle fasciculations and weakness. The central effects include nervousness, ataxia, apprehension, and seizures. Cattle and sheep commonly show severe depression. CNS stimulation in dogs and cats usually progresses to convulsions. Some OPs (eg, amidothioates) do not enter the brain easily, so that CNS signs are mild. Onset of signs after exposure is usually within minutes to hours but may be delayed for >2 days in some cases. Severity and course of intoxication is influenced principally by the dosage and route of exposure. In acute poisoning, the primary clinical signs may be respiratory distress and collapse followed by death due to respiratory muscle paralysis. In addition to brain and skeletal muscles, OPs are known to adversely affect other organ systems, including the cardiovascular, respiratory, hepatic, reproductive and developmental, and immune systems.

Diagnosis: An important diagnostic aid for OP poisoning is the determination of acetylcholinesterase (AChE) activity in blood and brain. Unfortunately, the depression of blood cholinesterase does not necessarily correlate with the severity of poisoning; signs are seen when brain AChE activity is inhibited >70%, and the enzyme in blood reflects, only in a general way, the levels in nervous tissue. The key factors appear to be the degree and rate at which the enzyme activity is reduced. Analyses performed after exposure may be negative, because OPs do not remain long in tissues as the parent compounds. Chlorinated OP compounds have greater potential for tissue residue. Frozen stomach and rumen contents should be analyzed for the pesticide, using GC-MS for identification, confirmation, and quantitation. Blood/serum and urine can also be analyzed for residue of OPs or their metabolites. More than 70% of OPs produce one or more of the six dialkylphosphates (dimethyl phosphate, diethyl phosphate, dimethyl thiophosphate, diethyl thiophosphate, dimethyl dithiophosphate, and diethyl dithiophosphate).

Lesions: Animals with acute OP poisoning have nonspecific or no lesions. Pulmonary

edema and congestion, hemorrhages, and edema of the bowel and other organs may be found. Animals surviving >1 day may become emaciated and dehydrated.

Treatment: Three categories of drugs are used to treat OP poisoning: 1) muscarinic receptor-blocking agents, 2) cholinesterase reactivators, and 3) emetics, cathartics, and adsorbents to decrease further absorption. Atropine sulfate blocks the central and peripheral muscarinic receptor-associated effects of OPs; it is administered to effect in dogs and cats, usually at a dosage of 0.2–2 mg/kg (cats at the lower end of the range), every 3–6 hr or as often as clinical signs indicate. For horses and pigs, the dosage is 0.1–0.2 mg/kg, IV, repeated every 10 min as needed; for cattle and sheep, the dosage is 0.6–1 mg/kg, one-third given IV, the remainder IM or SC, and repeated as needed. Atropinization is adequate when the pupils are dilated, salivation ceases, and the animal appears more alert. Animals initially respond well to atropine sulfate; however, the response diminishes after repeated treatments. Overtreatment with atropine should be avoided. Atropine does not alleviate the nicotinic cholinergic effects, such as muscle fasciculations and muscle paralysis, so death from massive overdoses of OPs can still occur. Including diazepam in the treatment reduced the incidence of seizures and increased survival of nonhuman primates experimentally.

An improved treatment combines atropine with the cholinesterase-reactivating oxime, 2-pyridine aldoxime methochloride (2-PAM, pralidoxime chloride). The dosage of 2-PAM is 20–50 mg/kg, given as a 5% solution IM or by slow IV (over 5–10 min), repeated at half the dose as needed. IV 2-PAM must be given very slowly to avoid musculoskeletal paralysis and respiratory arrest. Response to cholinesterase reactivators decreases with time after exposure; therefore, treatment with oximes must be instituted as soon as possible (within 24–48 hr). The rate at which the enzyme/organophosphate complex becomes unresponsive to reactivators (due to ageing phenomenon) varies with the particular pesticide.

Removal of the poison from the animal also should be attempted. If exposure was dermal, the animal should be washed with detergent and water (about room temperature) but without scrubbing and irritating the skin. Emesis should be induced if oral exposure occurred <2 hr previously; emesis is contraindicated if the animal is depressed. Oral administration of mineral oil decreases absorption of pesticide from the GI tract. Activated charcoal (1–2 g/kg as a water

slurry) adsorbs OPs and helps elimination in the feces. This is particularly recommended in cattle. Continued absorption of OPs from the large amount of ingesta in the rumen has caused prolonged toxicosis in cattle. Artificial respiration or administration of oxygen may be required. Phenothiazine tranquilizers, barbiturates, and morphine are contraindicated.

Intermediate Syndrome

Organophosphate-induced intermediate syndrome (IMS) has been seen in people and animals (particularly dogs and cats) acutely poisoned with a massive dose of an OP insecticide. OPs known to cause IMS include bromophos, chlorpyrifos, diazinon, dicotophos, dimethoate, disulfoton, fenthion, malathion, merphos, methamidophos, methyl parathion, monocrotophos, omethoate, parathion, phosmet, and trichlorfon. Clinically, IMS is characterized by acute paralysis and weakness in the areas of several cranial motor nerves, neck flexors, and facial, extraocular, palatal, nuchal, proximal limb, and respiratory muscles 24–96 hr after poisoning. IMS is a separate clinical entity from acute toxicity and delayed neuropathy. Generalized weakness, depressed deep tendon reflexes, ptosis, and diplopia are also evident. These symptoms may last for several days or weeks depending on the OP involved. Although the exact mechanism of action involved in IMS is unclear, the defect occurs at the neuromuscular junction (decreased AChE activity and expression of nicotinic receptors). Despite AChE inhibition, muscle fasciculations and hypersecretory activities are absent. There is no specific treatment; therapy relies on atropine sulfate and 2-PAM and should be continued for weeks.

DELAYED NEUROTOXICITY FROM TRIARYL PHOSPHATES

For some time, compounds known as triaryl phosphates (eg, triorthocresyl phosphate) have been used as flame retardants, plasticizers, lubricating oils, and hydraulic fluids. They are weak cholinesterase inhibitors but do inhibit "neurotoxic esterase" (NTE) present in the brain and spinal cord. A form of delayed neurotoxicity results from the inhibition and aging of NTE, often referred to as OP-induced delayed neuropathy (OPIDN). Triaryl phosphates have caused accidental poisonings in people and other species (mostly cattle). Some other OPs, including EPN, leptophos, parathion, haloxon, diisopropylphosphorofluoridate, and tetraethyl pyrophosphate, are known to

cause OPIDN, and field cases have been seen. The lesions associated with delayed neurotoxicity include demyelination of peripheral and spinal motor tracts due to loss of neurotoxic esterase function. Clinical signs associated with delayed neurotoxicity include muscle weakness and ataxia that progresses to flaccid paralysis. Signs are usually not manifest until 10–14 days after exposure to a neurotoxic triaryl phosphate. There are no specific antidotes.

PESTICIDE POTENTIATING AGENTS

Piperonyl butoxide is used as a potentiator or synergist in many pesticide formulations, including carbamates, organophosphates, organochlorines, pyrethrins, pyrethroids, and α -limonene. It decreases breakdown of these pesticides in the animal or insect's body by inhibiting mixed function oxidase enzymes and makes the pesticide more toxic to the insect—and the host. Animals that are debilitated or have decreased drug-metabolizing capability become more susceptible to the pesticide. However, toxins that must be activated in the body to a toxic form are frequently less toxic when piperonyl butoxide exposure occurs at the same time. This potentiating or synergistic effect has been seen in many species, including cats, dogs, rats, and people. Cimetidine, a drug that reduces stomach acid secretion by blocking gastric H_2 receptors, and the antibiotic chloramphenicol have the same effect.

SOLVENTS AND EMULSIFIERS

Solvents and emulsifiers are required in most liquid insecticide preparations. Usually they have low toxicity, but like the petroleum products (which many are), they must be considered as possible causes of poisoning. In direct treatment with pesticides, emulsification must be thorough, with an average droplet size of 5 microns (preferably smaller), or excessive amounts may stick to treated animals. Treatment should be as for petroleum product poisoning (see p 3053).

Acetone: GI irritation, narcosis, and kidney and liver damage are the main signs of acetone poisoning. Treatment consists of gastric lavage, oxygen, and a low-fat diet. Additional supportive treatment to alleviate clinical signs may be given.

Isopropyl Alcohol: Isopropyl alcohol poisoning signs are GI pain, cramps, vomiting, diarrhea, and CNS depression (dizziness, stupor, coma, and death from respiratory paralysis). The liver and kidneys

are reversibly affected. Dehydration and pneumonia may occur. Treatment consists of emetics, gastric lavage, milk, oxygen, and artificial respiration.

Methanol: Typical signs of methanol poisoning include nausea, vomiting, gastric pain, reflex hyperexcitability, opisthotonos, convulsions, fixed pupils, and acute peripheral neuritis. Large overdoses can lead to blindness. Toxic effects are due in part to the alcohol itself, and in part to formic acid produced by its oxidation. Treatment should include emetics (apomorphine) followed by gastric lavage with 4% sodium bicarbonate, saline laxative, oxygen therapy, sodium bicarbonate solution IV, and analgesics; however, the prognosis is poor. Intensive and prolonged

alkalinization is the mainstay of treatment. Ethanol retards the oxidation of methanol and may be given as an adjunct therapy.

SULFUR AND LIME-SULFUR

Sulfur and lime-sulfur are two of the oldest insecticides. Elemental sulfur is practically devoid of toxicity, although poisoning has occurred occasionally when large amounts were mixed in cattle feed. Specific toxic dosages are not known but probably exceed 4 g/kg. Lime-sulfur, which is a complex of sulfides, may cause irritation, discomfort, or blistering but rarely causes death. Treatment consists of removing residual material and applying bland protective ointments, plus any supportive measures that may be indicated.

METALDEHYDE POISONING

Metaldehyde, a cyclic polymer of acetaldehyde, is the active component in molluscicides used to control slugs and snails. It is commonly used in wet coastal areas worldwide. This neurotoxicant has been associated with poisoning in a variety of domestic and wildlife species, although most poisonings have been reported in dogs and are related to careless placement of bait. Metaldehyde may be combined with other agents such as carbamate insecticides to enhance efficacy. It is not considered to be a persistent chemical. Under typical application circumstances, metaldehyde may remain effective for as long as 10 days.

Etiology and Pathogenesis: Metaldehyde may be purchased in liquid, dust, granular, or pelleted formulations. The active ingredient may vary from 1.5%–5% in the formulation. The bait is highly palatable and potentially addictive, which often results in consumption of large quantities. Most avian and mammalian species are susceptible. The lethal oral dose ranges from ~100–600 mg/kg in various species.

After ingestion, metaldehyde undergoes partial hydrolysis in the stomach to produce acetaldehyde. Both metaldehyde and acetaldehyde are readily absorbed from the GI tract. The nature of the stomach contents and the rate of gastric emptying influence the rate of absorption and the onset of the clinical syndrome. After absorption, metaldehyde is rapidly

metabolized. Enterohepatic circulation may prolong retention of metaldehyde in the animal, but ultimately, both metaldehyde and acetaldehyde are excreted in the urine. Clinical manifestations are attributed primarily to metaldehyde, although acetaldehyde does play a role in the clinical syndrome. Metaldehyde exposure alters a variety of neurotransmitter concentrations and enzyme activities. Metaldehyde reduces concentrations of γ -aminobutyric acid, an inhibitory neurotransmitter that causes CNS excitation. Reduced concentrations of brain serotonin (5-hydroxytryptamine) and norepinephrine decrease the threshold for convulsions. Monoamine oxidase activity is increased after metaldehyde exposure. Increased muscle activity and the production of acidic metaldehyde metabolites cause severe electrolyte disturbances and metabolic acidosis.

Clinical Signs and Lesions: The clinical syndrome is similar in most species. Neurologic manifestations, which predominate, develop within 1–3 hr after ingestion. Severe muscle tremors, anxiety, hyperesthesia, ataxia, tachycardia, and hyperthermia may be evident initially. As the acidosis becomes more severe, depression and hyperpnea may become more evident. As the syndrome progresses, opisthotonos and continuous tonic convulsions that are unresponsive to external stimuli (in contrast to those in strychnine poisoning) are typical

manifestations. Emesis, diarrhea, hypersalivation, colic, cyanosis, sweating (horses), mydriasis, and nystagmus (cats) are often reported.

No consistent pathognomonic gross or histologic lesions are seen with metaldehyde poisoning. Hepatic, renal, and pulmonary congestion and intestinal ecchymotic and petechial hemorrhages, which may be associated with prolonged hyperthermia, are common. Neuronal degeneration in the brain and hepatic degeneration with cellular swelling are often present histologically.

Diagnosis: A history of exposure plus the presence of typical clinical disease is suggestive of metaldehyde poisoning. Stomach contents often have a distinctive acetaldehyde or apple cider–like odor. Rapid analysis of stomach contents submitted frozen for metaldehyde and acetaldehyde may be useful to confirm the diagnosis. Analysis of urine, blood, or liver may be useful but is often unreliable.

Neurologic, GI, and pulmonary disease caused by other agents may be confused with metaldehyde poisoning. Potential differential diagnoses include poisonings by strychnine, roquefortine, sodium fluoroacetate, zinc phosphide, bromethalin, organophosphate, carbamate, organochlorine or pyrethroid insecticides, cyanide, blue-green algae, or compost (tremorgonic mycotoxins). Nontoxic conditions such as epilepsy, various encephalitic infections, lysosomal storage diseases, or metabolic diseases such as

hypocalcemia also may resemble metaldehyde poisoning.

Treatment: There is no specific treatment for metaldehyde poisoning, although aggressive symptomatic treatment during the first 24 hr will enable most affected animals to make a full recovery within 2–3 days. Activated charcoal and cathartics may be administered to assist in decontamination and to reduce enterohepatic cycling of metaldehyde. Diazepam (2–5 mg/kg, IV, to effect) may be used to control neurologic manifestations. Barbiturate treatment should be considered with caution, because barbiturates compete with acetaldehyde metabolism and induce cytochrome P450 enzymes involved in metaldehyde metabolism. Gas anesthesia may also be a useful alternative. Administration of IV fluids containing sodium lactate or sodium bicarbonate is essential to correct the metabolic acidosis and electrolyte imbalance. Cold water to correct the hyperthermia, methocarbamol (150 mg/kg, IV) to produce muscle relaxation, and dextrose (IV) or calcium borogluconate (IV) to minimize liver damage may be helpful. Xylazine is an effective treatment in horses to reduce neurologic manifestations. Treatment options, dosages, and duration of treatment vary considerably from species to species.

Metaldehyde and acetaldehyde are rapidly eliminated. Consequently, tissue residues in food-producing animals are not a major concern. Withdrawal times, if established, will be relatively short.

ARSENIC POISONING

The ubiquitous element arsenic (As) is a nonmetal or metalloid in group V on the periodic chart. It is often referred to as arsenic metal and for toxicologic purposes is classified as a metal. It exists in several forms and has a long history of various uses, including insecticides for animals, wood preservatives, herbicides, and even some medicinal uses. It is responsible for many poisonings in people and animals.

Arsenic poisoning is caused by several different forms of the element; the form may determine the toxicity. Arsenic is found as inorganic and organic forms with valences of +3 and +5. Arsenite (As^{+3}) is more toxic than arsenate (As^{+5}). Toxicity varies with factors such as oxidation state of the arsenic,

solubility, species of animal involved, and duration of exposure. Therefore, the toxic effects produced by phenylarsonic feed additives and other inorganic and organic compounds must be distinguished. (See also *HERBICIDE POISONING*, p 2969.)

INORGANIC ARSENICALS

Trivalent arsenicals, or arsenites, are more soluble and therefore more toxic than the pentavalent, or arsenate, compounds. These include arsenic trioxide, arsenic pentoxide, sodium and potassium arsenate, sodium and potassium arsenite, and lead or calcium arsenate. The lethal oral dose of sodium arsenite in most species is from 1–25 mg/kg.

Cats may be more sensitive. In livestock, arsenates are 5–10 times less toxic than arsenites. Decreased use of these compounds as pesticides, ant baits, and wood preservatives has made poisonings less frequent. Arsenites were used to some extent as dips for tick control. Lead arsenate was sometimes used as a taeniocide in sheep. Many of these compounds are no longer used in the USA but may still be available in other countries.

Toxicokinetics and Mechanism of Action:

Soluble forms of arsenic compounds are well absorbed orally. After absorption, most of the arsenic is bound to RBCs; it distributes to several tissues, with the highest levels found in liver, kidneys, heart, and lungs. In subchronic or chronic exposures, arsenic accumulates in skin, nails, hooves, sweat glands, and hair. Most of the absorbed arsenic is excreted in the urine as inorganic arsenic or in methylated form.

The mechanism of action of arsenic toxicosis varies with the type of arsenical compound. Generally, tissues rich in oxidative enzymes, such as the GI tract, liver, kidneys, lungs, endothelium, and epidermis, are considered more vulnerable to arsenic damage. Trivalent inorganic and aliphatic organic arsenic compounds exert their toxicity by interacting with sulfhydryl enzymes, resulting in disruption of cellular metabolism. Arsenate can uncouple oxidative phosphorylation.

Clinical Findings: Poisoning is usually acute, with major effects on the GI tract and cardiovascular system. Arsenic has a direct effect on the capillaries, causing damage to microvascular integrity, transudation of plasma, loss of blood, and hypovolemic shock. Profuse watery diarrhea, sometimes tinged with dark blood, is characteristic, as are severe colic, dehydration, weakness, depression, weak pulse, and cardiovascular collapse. Onset is rapid, and signs are usually seen within a few hours (or up to 24 hr). The course may run from hours to several days, depending on the quantity ingested. In peracute poisoning, most animals may simply be found dead, and a few will be found dead without any lesions.

Lesions: In peracute toxicosis, there are usually some lesions in the GI tract. Inflammation and reddening of GI mucosa (local or diffuse) may be seen, followed by edema, rupture of blood vessels, and necrosis of epithelial and subepithelial tissue. In ruminants, hyperemic “paintbrush” lesions may be seen on the serosal surface of the omasum, and the abomasal

mucosa may be hyperemic. Necrosis may progress to perforation of the gastric or intestinal wall. GI contents are often fluid, foul smelling, and blood tinged; they may contain shreds of epithelial tissue. There is diffuse inflammation of the liver, kidneys, and other visceral organs. The liver may have fatty degeneration and necrosis, and the kidneys have tubular damage. In cases of cutaneous exposure, the skin may exhibit necrosis and be dry or leathery.

Diagnosis: Chemical determination of arsenic in tissues (liver or kidney) or stomach contents provides confirmation. Liver and kidneys of healthy animals rarely contain >0.1 ppm arsenic (wet wt); toxicity is associated with tissue concentrations >3 ppm (wet wt). The determination of arsenic in stomach contents is of value usually within the first 24–48 hr after ingestion. The concentration of arsenic in urine can be high for several days after ingestion. Drinking water containing >0.25 ppm arsenic is considered potentially toxic, especially for large animals.

Treatment: In animals with recent exposure and no clinical signs, emesis should be induced (in capable species), followed by activated charcoal with a cathartic (efficacy of charcoal in arsenic toxicosis remains to be determined) and then oral administration of GI protectants (small animals, 1–2 hr after charcoal) such as kaolin-pectin, and fluid therapy as needed. In animals already showing clinical signs, aggressive fluid therapy, blood transfusion (if needed), and administration of dimercaprol (British anti-lewisite, 4–7 mg/kg, IM, tid for 2–3 days or until recovery) is recommended. In large animals, thioctic acid (lipoic acid or α -lipoic acid) may be used alone (50 mg/kg, IM, tid, as a 20% solution) or in combination with dimercaprol (3 mg/kg, IM, every 4 hr for the first 2 days, qid for the third day, and bid for the next 10 days or until recovery). In large animals, the efficacy of dimercaprol alone is questionable. Sodium thiosulfate has also been used, PO, at 20–30 g in 300 mL of water in horses and cattle, one-fourth this dose in sheep and goats, and 0.5–3 g in small animals or as a 20% solution, IV, at 30–40 mg/kg, bid-tid for 3–4 days or until recovery. The water-soluble analogues of dimercaprol, 2,3-dimercaptopropane-1-sulfonate (DMPS) and dimercaptosuccinic acid (DMSA), are considered to be less toxic and more effective and could be given orally. D-Penicillamine is reportedly an effective arsenic chelator in people. It has a wide margin of safety and could be used in animals at 10–50 mg/kg, PO, tid-qid for 3–4 days. Supportive therapy may be of even greater

value, particularly when cardiovascular collapse is imminent, and should involve IV fluids to restore blood volume and correct dehydration. Kidney and liver function should be monitored during treatment.

ORGANIC ARSENICALS

Phenylarsonic organic arsenicals are relatively less toxic than inorganic compounds or aliphatic and other aromatic organic compounds.

Aliphatic organic arsenicals include cacodylic acid and acetarsonic acid. These were historically used as stimulants in large animals, but their use is now uncommon. Some aliphatic arsenicals such as monosodium methanearsonate (MSMA) and disodium methanearsonate (DSMA) are occasionally used as herbicides or grassburr and crabgrass killers. Ruminants, especially cattle, are very sensitive to MSMA and DSMA. Clinical signs, lesions, and treatment of aliphatic organic arsenicals are similar to those of inorganic arsenicals, except that ruminants may have necrosis of the mucosa of the rumen and omasum and gelatinous serosal edema of the omasum and abomasum.

Aromatic organic arsenicals include trivalent phenylorganics, such as thiacetarsamide and arspenamine for the treatment of adult heartworms in dogs, and pentavalent compounds such as phenylarsonic acids and their salts. Thiacetarsamide and arspenamine are no longer used commonly, especially since the introduction of melarsonine dihydrochloride (*see also* HEARTWORM DISEASE, p 127).

Phenylarsonic compounds were widely used as feed additives to improve production in swine and poultry rations and to treat dysentery in pigs. The three major compounds in this class are arsanilic acid, roxarsone (4-hydroxy-3-nitrophenylarsonic acid), and nitarsone (4-nitrophenylarsonic acid).

Etiology: Toxicosis results from an excess of arsenic-containing additives in pig or

poultry diets. Severity and rapidity of onset are dose-dependent. Signs may be delayed for weeks after incorporation of 2–3 times the recommended (100 ppm) levels or may occur within days when the excess is >10 times the recommended levels. Chickens are tolerant of arsanilic acid; however, roxarsone can produce toxicosis in turkeys at only twice the recommended dose (50 ppm). In pigs, roxarsone also has a higher toxicity than other phenylarsonics.

Clinical Findings and Diagnosis: The earliest sign in pigs may be reduced weight gain, followed by incoordination, posterior paralysis, and eventually quadriplegia. Animals remain alert and maintain good appetite. Blindness is characteristic of arsanilic acid intoxication but not of other organic arsenicals. In ruminants, phenylarsonic toxicosis is similar to inorganic arsenic poisoning. There are usually no specific lesions present in phenylarsonic poisoning. Demyelination and gliosis of peripheral nerves, the optic tract, and optic nerves are usually seen on histopathology. Analyses of feed for the presence of high levels of phenylarsonics confirm the diagnosis.

Phenylarsonic poisoning in pigs should be differentiated from salt poisoning, insecticide poisoning, and pseudorabies. In cattle, arsenic poisoning should be differentiated from other heavy metal poisoning, insecticide poisoning, and infectious diseases such as bovine viral diarrhea.

Treatment and Prognosis: There is no specific treatment, but the neurotoxic effects are usually reversible if the offending feed is withdrawn within 2–3 days of onset of ataxia. Once paralysis occurs, the nerve damage is irreversible. Blindness is usually irreversible, but animals retain their appetite, and weight gain is good if competition for food is eliminated. Recovery may be doubtful when the exposure is long and the onset of intoxication slow.

COPPER POISONING

Acute or chronic copper poisoning is encountered in most parts of the world. Sheep are affected most often, although other species are also susceptible. In various breeds of dogs, especially Bedling-

ton Terriers, an inherited sensitivity to copper toxicosis similar to Wilson disease in people has been identified. Chronic copper poisoning has been reported in other breeds of dogs, including Labrador Retrievers, West

Highland White Terriers, Skye Terriers, Keeshonds, American Cocker Spaniels, and Doberman Pinschers. Acute poisoning is usually seen after accidental administration of excessive amounts of soluble copper salts, which may be present in anthelmintic drenches, mineral mixes, or improperly formulated rations.

Many factors that alter copper metabolism influence chronic copper poisoning by enhancing the absorption or retention of copper. Low levels of molybdenum or sulfate in the diet are important examples. Primary chronic poisoning is seen most commonly in sheep when excessive amounts of copper are ingested over a prolonged period. The toxicosis remains subclinical until the copper that is stored in the liver is released in massive amounts. Increased liver enzymes may provide an early warning of the pending crisis. Blood copper concentrations increase suddenly, causing lipid peroxidation and intravascular hemolysis. The hemolytic crisis may be precipitated by many factors, including transportation, handling, weather conditions, pregnancy, lactation, strenuous exercise, or a deteriorating plane of nutrition.

Phytogenous and hepatogenous factors influence secondary chronic copper poisoning. Phytogenous chronic poisoning is seen after ingestion of plants, such as subterranean clover (*Trifolium subterraneum*), that produce a mineral imbalance and result in excessive copper retention. The plants that are not hepatotoxic contain normal amounts of copper and low levels of molybdenum. The ingestion of plants such as *Heliotropium europaeum* or *Senecio* spp (see p3150) for several months may cause hepatogenous chronic copper poisoning. These plants contain hepatotoxic alkaloids, which result in retention of excessive copper in the liver. In dogs with liver diseases such as chronic active hepatitis (CAH), the primary clinical signs may resemble those of chronic copper poisoning, which can be attributed to the liver damage and subsequent retention of excessive copper; however, it is not clear whether CAH causes the accumulation of copper in the liver or is the result of accumulation.

Acute poisoning may follow intakes of 20–100 mg of copper/kg in sheep and young calves and of 200–800 mg/kg in mature calves. Chronic poisoning of sheep may occur with daily intakes of 3.5 mg of copper/kg when grazing pastures that contain 15–20 ppm (dry matter) of copper and low levels of molybdenum. Clinical disease may occur in sheep or camelid species that ingest cattle rations, which normally contain higher levels of copper, or when their water is supplied via

copper plumbing; cattle and goats are more resistant to copper poisoning than sheep and thus are not affected in these instances. Species-specific diets with respect to copper are recommended to minimize the occurrence of chronic copper poisoning. Breed differences related to the susceptibility to chronic copper poisoning have been reported in sheep and goats. Young calves or sheep injected with soluble forms of copper may develop acute clinical signs of toxicity without evidence of a hemolytic crisis. Copper is used as a feed additive for pigs at 125–250 ppm; levels >250 ppm are dangerous—although as for sheep, other factors may be protective, eg, high levels of protein, zinc, or iron. Chronic copper toxicosis is more likely to occur with low dietary intake of molybdenum and sulfur. Reduced formation of copper molybdate or copper sulfide complexes in tissues impairs the excretion of copper in urine or feces.

Clinical Findings: Acute copper poisoning causes severe gastroenteritis characterized by abdominal pain, diarrhea, anorexia, dehydration, and shock. Hemolysis and hemoglobinuria may develop after 3 days if the animal survives the GI disturbances. The sudden onset of clinical signs in chronic copper poisoning is associated with the hemolytic crisis. The time of onset is influenced by the concentration of copper in the diet. Signs in affected animals include depression, lethargy, weakness, recumbency, rumen stasis, anorexia, thirst, dyspnea, pale mucous membranes, hemoglobinuria, and jaundice. Several days or weeks before the hemolytic crisis, liver enzymes, including ALT and AST, are usually increased. During the hemolytic crisis, methemoglobinemia, hemoglobinemia, and decreases in PCV and blood glutathione are usually seen. In camelid species such as alpacas or llamas, no hemolytic crisis is seen, although extensive liver necrosis remains a consistent manifestation. Morbid animals often die within 1–2 days. Herd morbidity is often <5%, although usually >75% of affected animals die. Losses may continue for several months after the dietary problem has been rectified. Severe hepatic insufficiency is responsible for early deaths. Animals that survive the acute episode may die of subsequent renal failure. Photosensitization may occur in association with chronic copper poisoning, reflecting the hepatotoxicity common to both syndromes. Cirrhosis of the liver is also associated with the syndrome in dogs.

Lesions: Acute copper poisoning produces severe gastroenteritis with erosions and

ulcerations in the abomasum of ruminants. Icterus develops in animals that survive >24 hr. Tissues discolored by icterus and methemoglobin are characteristic of chronic poisoning. Swollen, gunmetal-colored kidneys, port-wine-colored urine, and an enlarged spleen with dark brown-black parenchyma are manifestations of the hemolytic crisis. The liver is enlarged and friable. Histologically, there is centrilobular hepatic and renal tubular necrosis.

Diagnosis: Evidence of blue-green ingesta and increased fecal (8,000–10,000 ppm) and kidney (>15 ppm, wet wt) copper levels are considered significant in acute copper poisoning. In chronic poisoning, blood and liver copper concentrations are increased during the hemolytic period. Blood concentrations often rise to 5–20 mcg/mL, as compared with normal levels of ~1 mcg/mL. Liver concentrations >150 ppm (wet wt) are significant in sheep. The concentration of copper in the tissue must be determined to eliminate other causes of hemolytic disease. Molybdenum tissue concentrations should be evaluated to determine whether the syndrome is due to primary or secondary chronic copper poisoning.

Treatment and Control: Often, treatment is not successful. The prognosis is poor in all species. GI sedatives and symptomatic treatment for shock may be useful in acute toxicity. Penicillamine (50 mg/kg/day, PO, for 6 days) or calcium versenate may be useful if administered in the early stages of disease to enhance copper excretion. Vitamin C (500 mg/day/sheep, SC) has been shown to reduce

oxidative damage to RBCs during the hemolytic crisis. Ammonium tetrathiomolybdate (1.7 mg/kg, IV, every other day for 6 days) is effective for the treatment and prevention of copper poisoning. This treatment, which reduces copper absorption and enhances copper elimination, should be used conservatively. A withdrawal period of ~10 days is required for this medication. Daily oral administration of ammonium molybdate (100 mg) and sodium thiosulfate (1 g) for 3 wk reduces losses in affected lambs. Dietary supplementation with zinc acetate (250 ppm) may be useful to reduce the absorption of copper. Plant eradication or reducing access to plants that cause phyto-genous or hepatogenous copper poisoning is desirable. Primary chronic or phyto-genous poisoning may be prevented by top-dressing pastures with 1 oz of molybdenum per acre (70 g/hectare) in the form of molybdenized superphosphate or by molybdenum supplementation or restriction of copper intake. High-risk flocks of sheep may be supplemented with sodium thiosulfate in the diet to prevent or control chronic copper poisoning. In dogs, genetic testing is available to identify carriers of the autosomal recessive gene associated with abnormal copper accumulation, although the mode of inheritance is not known for all susceptible breeds. Periodic liver biopsies, tissue copper determination, and liver enzyme assessment may also be useful to evaluate disease status. In addition to previously described treatments, zinc supplementation and prednisone or prednisolone administration enhance copper excretion and limit development of liver disease.

FLUORIDE POISONING

(Fluorosis)

Fluoride exposure from the environment has been associated with natural contamination of rock, soil, and water or from industrial waste or smelting processes. Fluoride compounds have been added to human water supplies at concentrations of ~1 mg/kg to reduce dental caries. This recommendation is not universally accepted. Both acute and chronic toxicoses are reported with fluoride ingestion. Maximum tolerance levels in animal feeds

range from ~20–50 mg/kg (dry weight) in most species. In poultry, as much as 200 mg/kg can be tolerated. These tolerances may vary depending on age, duration of exposure, and nutritional status. Animals with a long, productive life span such as dairy cattle are more susceptible.

Etiology and Pathogenesis: Fluorides are found naturally in rock phosphates and limestone. Industrial wastes associated with

fertilizer and mineral supplement production are frequent sources of fluoride exposure. Metal ores associated with steel and aluminum processing are common industrial sources. Fluoride dusts dispersed downwind from these sources may contaminate forage crops for many kilometers. Forage crops grown on contaminated soil may contain increased concentrations of fluoride associated with physical contamination with soil particulates. There is minimal direct uptake of fluoride by the plant. With the potential of fluoride contamination in many feed and water sources, it is recommended that feed-grade phosphates contain < 1% fluoride. Acute fluoride exposure at high concentrations will cause corrosive damage to tissues. In contrast, chronic exposure, which is seen more frequently, causes delayed or impaired mineralization of bones and teeth. The solubility of fluoride correlates generally with the degree of toxicity. Fluoride is known to interact with various elements, including aluminum, calcium, phosphorus, and iodine. Fluoride is a cellular poison that interferes with the metabolism of essential metals such as magnesium, manganese, iron, copper, and zinc. Because bacterial metabolism may be affected in a similar manner, this attribute accounts for the use of fluoride in dental hygiene products. Soluble fluoride is rapidly absorbed; ~50% is excreted by glomerular filtration. More than 95% of the fluoride that is retained is deposited in the bones and teeth, forming hydroxyapatite after the interference with calcium metabolism and replacement of hydroxyl ions. At low levels of fluoride exposure, the solubility of the enamel is reduced, resulting in protection. At higher levels of exposure, the enamel becomes dense and brittle. If exposure occurs during pregnancy, developing bones and teeth are severely affected. Faulty, irregular mineralization of the matrix associated with altered ameloblastic, odontoblastic, or osteoblastic activity ultimately results in poor enamel formation, exostosis, sclerosis, and osteoporosis.

Clinical Findings: Acute poisoning associated with massive ingestion of ascaricides (sodium fluoride), rodenticides (sodium fluorosilicate), or oral dental products will produce clinical disease within 2 hr. The fatal dosage of sodium fluoride is ~5–10 mg/kg. Toxic manifestations may be evident after consumption of ~1 mg/kg. Serum calcium and magnesium concentrations decline rapidly after the onset of the clinical syndrome. Severe

gastroenteritis, salivation, restlessness, sweating, anorexia, muscle weakness, stiffness, dyspnea, ventricular tachycardia, and clonic convulsions followed by depression and death are typically seen. Chronic fluorosis is characterized by unthrifty animals with skeletal and dental abnormalities. Reduced feed and water intake accompanied by poor weight gain and milk production reflect dental lesions and impaired mastication. Mottled, chalky, pitted and stained enamel, and uneven and excessive wear on the teeth are frequently seen. Dental pain manifested by lapping of drinking water may be apparent. Skeletal abnormalities associated with increased bone resorption and remodeling produces severe lameness, stiffness, abnormal hoof growth, and exostoses. In later stages of the syndrome, severely affected cattle may be forced to move on their knees because of spurring and bridging of joints. Periosteal hyperostosis is seen on ribs. Metabolically active and growing bones of young animals are more severely affected. Anemia and hypothyroidism manifested by reduced T_3 and T_4 levels plus reduced serum calcium concentrations are often present.

Lesions: Severe GI inflammation and degenerative changes in other organs such as the liver, kidney, and lungs reflect the cytotoxic effects of acute fluorosis. After chronic exposure during pregnancy, offspring are more severely affected. Bilateral and symmetrical skeletal abnormalities are present. The bones are chalky white with disrupted osteogenesis, accelerated bone remodeling, and resorption in association with production of abnormal bone osteoid that results in exostoses, sclerosis, and osteoporosis. The mandible, ribs, metacarpals, and metatarsals are most often affected. Exostoses are most evident in the long bones. In addition to the mottled, chalky, stained teeth exhibiting uneven wear, eruption of permanent incisor teeth may be delayed.

Diagnosis: A diagnosis of acute fluoride poisoning should be based on a history of exposure and typical clinical or pathologic manifestations. Confirmation with urine or serum measurements should be interpreted with caution, because rapid, time-dependent elimination of fluoride occurs. The measurement of serum calcium and magnesium concentrations may provide supportive evidence. Chronic fluorosis may require many months to develop. Fluoride concentrations in tissues must be considered in association with history, clinical disease, and necropsy findings. Animals exhibiting skeletal and

dental abnormalities manifested by lameness, osteoporosis, anorexia, or reduced productivity should be evaluated for chronic fluorosis. Other disease syndromes such as arthritis; calcium, phosphorous, or vitamin D deficiency; metal toxicities such as molybdenum, selenium, or arsenic; and ergotism may be confused with chronic poisoning. In addition to tissue analysis, radiographs and histologic evaluation may provide useful information. In livestock, normal fluoride concentrations in the diet range from ~20–50 mg/kg. Depending on the duration of exposure and species susceptibility, concentrations in the diet ranging from 100–300 mg/kg may produce chronic poisoning. Water concentrations >30 mg/L are considered toxic. In young dairy cattle with a lengthy lifetime production potential, tolerance levels should be reduced by at least 2-fold. Because fluoride does not accumulate in soft tissue, analysis of liver and kidney has limited usefulness. In livestock, normal plasma concentrations are <0.2 mg/L, whereas concentrations ranging from 0.7–1.9 mg/L are consistent with poisoning. Corresponding urinary concentrations <0.5 mg/L are normal. Toxic concentrations based on recent exposure range from 14–120 mg/L. Fluoride concentrations in bones and teeth may reach levels as high as 1,500 mg/kg and 1,000 mg/kg, respectively, without adverse effects.

Concentrations ranging from 6,000–13,000 mg/kg and 7,500–11,000 mg/kg, respectively, are consistent with a diagnosis of chronic fluorosis in livestock. Plasma concentrations may rise substantially once the skeletal concentrations of fluoride approach saturation.

Treatment and Control: Animals developing acute poisoning may be administered calcium gluconate (IV) and magnesium hydroxide or milk orally to minimize fluoride absorption, although the prognosis may remain poor if massive amounts of fluoride were ingested. Once manifestations of chronic fluorosis develop, treatment is ineffective. The primary objective should be directed toward prevention. In many instances, it may be difficult or impractical to remove livestock from contaminated areas. Supplementation with calcium carbonate, aluminum salts, magnesium metasilicate, or boron will reduce absorption or enhance excretion. It is recommended that livestock consume supplements and mineral mixes containing <1% fluoride content. If it is impractical to limit fluoride exposure, raising species with a relatively short production life, such as poultry, pigs, or sheep, should be considered. Reducing fluoride exposure of young or pregnant animals may limit the development of chronic fluorosis.

IRON TOXICITY IN NEWBORN PIGS

Reports of toxicity after SC or IM injection of iron preparations in newborn piglets are sporadic, and the risk is not high; however, toxicity does occur occasionally. In some litters, death occurs quickly, from 30 min to 6 hr after injection; in others, death is delayed for 2–4 days. (See also NONREGENERATIVE ANEMIAS, p 12.)

Toxicity may be seen in three forms. In the first form, damage to the muscles around the injection site causes potassium, among other substances, to be released; the blood potassium level rises and interferes with cardiac function. Usually, the whole litter is affected. Piglets may appear anemic, become weak, cannot stand, and have muscle tremors followed by convulsions. Respiratory distress may be seen. There is swelling at the injection site. On necropsy, skin and muscles may appear pale, and there

is edema and a brownish black discoloration at the injection site. Waxy degeneration of skeletal and heart muscle may be seen; there may be hemorrhages in the heart and necrosis of the liver and kidneys.

In the second, less acute form of toxicity, the excess iron appears to block the body's defense mechanisms by overwhelming the phagocytic cells, which increases the likelihood of infection. Death occurs in ~2–4 days. In young piglets, the most likely infection is an *Escherichia coli* enteritis and, although some of the changes seen in the first form may be seen at necropsy, they are less obvious, and the enteritis contributes markedly to death.

The most important precipitating factor of iron toxicosis in pigs is a low vitamin E or selenium status of the sow. If either nutrient is low in the sow, pigs will either be born

deficient in vitamin E or selenium or the colostrum will not be able to provide adequate amounts of these nutrients to meet the antioxidant needs of nursing piglets. Supplementing the sow's diet with 50 IU of vitamin E/kg and 0.15 mg of selenium/kg will improve the status of the sow and prevent iron toxicity in the piglets. Injections of vitamin E/selenium during late gestation may also help prevent iron toxicity in piglets.

A third, more rare form of toxicity is associated with **calciophylaxis**, the massive mobilization of calcium after injection of iron preparations, both in the presence and absence of supplementary vitamin D. It occurs within several days of iron injection and is associated with development of hard swellings at injection sites. Death may occur, and calcification in other parts of the body may be seen at necropsy.

LEAD POISONING

Lead poisoning in animals and people is a major concern worldwide. Poisoning in animal populations may serve as a sentinel to assess the extent of environmental contamination and human health problems related to lead. In veterinary medicine, lead poisoning is most common in dogs and cattle. Lead poisoning in other species is limited by reduced accessibility, more selective eating habits, or lower susceptibility. In cattle, many cases are associated with seeding and harvesting activities when used oil and battery disposal from machinery is handled improperly. With the elimination of tetraethyl lead from gasoline in many countries, the number of lead poisoning cases attributed to oil consumption has declined. Other sources of lead include paint, linoleum, grease, lead weights, lead shot, and contaminated foliage growing near smelters or along roadsides. To prevent future occurrences of lead poisoning, it is crucial to identify the source. Lead poisoning is also encountered in urban environments and during the renovation of old houses that have been painted with lead-based paint, leading to exposure of small animals and children. The consumption, through grooming, of dust containing lead has been reported in cats. Improper disposal of lead-poisoned animal carcasses may result in toxicoses in nontarget scavenger animals. Scavenging by endangered species such as the condor raises unique concerns.

Pathogenesis: Absorbed lead enters the blood and soft tissues and eventually redistributes to the bone. The degree of absorption and retention is influenced by dietary factors such as calcium or iron levels. In ruminants, particulate lead lodged in the reticulum slowly dissolves and releases significant quantities of lead. Lead

has a profound effect on sulfhydryl-containing enzymes, the thiol content of erythrocytes, antioxidant defenses, and tissues rich in mitochondria, which is reflected in the clinical syndrome. In addition to the cerebellar hemorrhage and edema associated with capillary damage, lead is also irritating, immunosuppressive, gametotoxic, teratogenic, nephrotoxic, and toxic to the hematopoietic system.

Clinical Findings: Acute lead poisoning is more common in young animals. The prominent clinical signs are associated with the GI and nervous systems. In cattle, signs that appear within 24–48 hr of exposure include ataxia, blindness, salivation, spastic twitching of eyelids, jaw champing, bruxism, muscle tremors, and convulsions.

Subacute lead poisoning, usually seen in sheep or older cattle, is characterized by anorexia, rumenstasis, colic, dullness, and transient constipation, frequently followed by diarrhea, blindness, head pressing, bruxism, hyperesthesia, and incoordination.

Chronic lead poisoning, occasionally seen in cattle, may produce a syndrome that has many features in common with acute or subacute lead poisoning. Impairment of the swallowing reflexes frequently contributes to development of aspiration pneumonia. Embryotoxicity and poor semen quality may contribute to infertility.

GI abnormalities, including anorexia, colic, emesis, and diarrhea or constipation are predominant manifestations in dogs. Anxiety, hysterical barking, jaw champing, salivation, blindness, ataxia, muscle spasms, opisthotonos, and convulsions may develop. CNS depression rather than CNS excitation may be evident in some dogs. In horses, lead poisoning usually produces a chronic syndrome characterized by weight

loss, depression, weakness, colic, diarrhea, laryngeal or pharyngeal paralysis (roaring), and dysphagia that frequently results in aspiration pneumonia.

In birds, anorexia, ataxia, loss of condition, wing and leg weakness, and anemia are the most notable signs.

Lesions: Animals that die from acute lead poisoning may have few observable gross lesions. Oil or flakes of paint or battery may be evident in the GI tract. The caustic action of lead salts causes gastroenteritis. In the nervous system, edema, congestion of the cerebral cortex, and flattening of the cortical gyri are present. Histologically, endothelial swelling, laminar cortical necrosis, and edema of the white matter may be evident. Tubular necrosis and degeneration and intranuclear acid-fast inclusion bodies may be seen in the kidneys. Osteoporosis has been described in lambs. Placentitis and accumulation of lead in the fetus may result in abortion.

Diagnosis: Lead concentrations in various tissues may be useful to evaluate excessive accumulation and to reflect the level or duration of exposure, severity, and prognosis and the success of treatment. Concentrations of lead in the blood at 0.35 ppm, liver at 10 ppm, or kidney cortex at 10 ppm are consistent with a diagnosis of lead poisoning in most species. Many countries have deemed blood lead concentrations >0.05 – 0.10 ppm to be a notifiable disease in food-producing animals. Inspection or clearance by a regulatory veterinary officer or biosecurity inspector is mandatory before shipment for food consumption is permitted.

Hematologic abnormalities, which may be indicative but not confirmatory of lead poisoning, include anemia, anisocytosis, poikilocytosis, polychromasia, basophilic stippling, metarubricytosis, and hypochromia. Blood or urinary δ -aminolevulinic acid and free erythrocyte protoporphyrin levels are sensitive indicators of lead exposure but may not be reliable indicators of clinical disease. Radiologic examination may be useful to determine the magnitude of lead exposure.

Lead poisoning may be confused with other diseases that cause nervous or GI abnormalities. In cattle, such diseases may include polioencephalomalacia, nervous coccidiosis, tetanus, hypovitaminosis A, hypomagnesemic tetany, nervous acetone-mia, organochlorine insecticide poisoning, arsenic or mercury poisoning, brain abscess or neoplasia, rabies, listeriosis, and *Haemophilus* infections.

In dogs, rabies, distemper, and hepatitis may appear similar to lead poisoning.

Treatment: If tissue damage is extensive, particularly to the nervous system, treatment may not be successful. In livestock, calcium disodium edetate (Ca-EDTA) is given IV or SC (110 mg/kg/day) divided bid for 3 days; this treatment should be repeated 2 days later. In dogs, a similar dose divided qid is administered SC in 5% dextrose for 2–5 days. After a 1-wk rest period, an additional 5-day treatment may be required if clinical signs persist. No approved veterinary product containing Ca-EDTA is currently commercially available.

Thiamine (2–4 mg/kg/day, SC) alleviates clinical manifestations and reduces tissue deposition of lead. Combined Ca-EDTA and thiamine treatment appears to produce the most beneficial response.

D-Penicillamine can be administered PO to dogs (110 mg/kg/day) for 2 wk. However, undesirable adverse effects such as emesis and anorexia have been associated with this treatment. D-Penicillamine is not recommended for livestock. Succimer (meso 2,3-dimercaptosuccinic acid [DMSA]) is a chelating agent that has proved to be effective in dogs (10 mg/kg, PO, tid for 10 days) and is also useful in birds. Fewer adverse effects have been associated with DMSA than with Ca-EDTA.

Cathartics such as magnesium sulfate (400 mg/kg, PO) or a rumenotomy may be useful to remove lead from the GI tract. In cattle, surgery to remove particulate lead material from the reticulum after the ingestion of batteries is rarely successful. Barbiturates or tranquilizers may be indicated to control convulsions. Chelation therapy, in combination with antioxidant treatment, may limit oxidative damage associated with acute lead poisoning. Antioxidants such as N-acetylcysteine (50 mg/kg/day, PO) have been used in combination with DMSA.

Mobilization of lead at parturition, excretion of lead into milk, and lengthy withdrawal times in food-producing animals raise considerable controversy regarding the rationale for treatment from both public health and animal management perspectives. The half-life of lead in the blood of cattle ingesting particulate lead is usually >9 wk. Withdrawal times, which may be >1 yr, should be estimated by periodic monitoring of blood lead concentrations. In a herd of cattle with confirmed cases of lead poisoning, all potentially exposed cattle should be evaluated. A small but significant portion of the asymptomatic cattle may have concentrations of lead in tissues that exceed recognized food safety standards.

MERCURY POISONING

Historically, mercury poisoning was a common occurrence in both human and animal populations. The replacement of mercury products used for medicinal, agricultural, or industrial purposes has resulted in a decline in acute and chronic poisoning, although many wildlife species remain at risk. Predator species considered to be near the top of the food chain, such as fish, seals, polar bears, and various bird species, bioaccumulate significant quantities of mercury from dietary sources. Commercial fish products such as tuna have been associated with chronic poisoning in human and animal (cats) populations. Mercury exists in a variety of chemical forms, including elemental mercury (eg, thermometers, light bulbs), inorganic mercurial (mercuric or mercurous) salts (eg, batteries, latex paints), and organic mercury (aryl, methyl, or ethyl). Fossil fuels represent an important environmental source of mercury. In the environment, inorganic forms of mercury are converted to methylmercury under anaerobic conditions in the sediment of most water bodies. Similar conversions may also occur in the body.

Pathogenesis: The physical, chemical, and kinetic properties of the various forms of mercury play an important role influencing the clinical manifestations, the extent and nature of lesions, and the tissue distribution of mercury. The organic forms of mercury, primarily methylmercury, are lipid soluble and well absorbed orally. Consequently, bioaccumulation is extensive in tissues such as the brain, kidney, and fetus. Methylmercury interferes with metabolic activity, resulting in degeneration and necrosis in many tissues, although the brain and fetus are more susceptible. In the brain, histologically, neuronal degeneration and perivascular cuffing is evident in the cerebrocortical grey matter. Cerebellar atrophy or hypoplasia and Purkinje cell degeneration are seen. Encephalomalacia, the loss of myelin, and necrosis of axons may also be evident. Methylmercury is mutagenic, carcinogenic, embryotoxic, and highly teratogenic. The inorganic forms of mercury, including elemental mercury, are poorly absorbed after dermal exposure. Elemental mercury vapors are inhaled and rapidly absorbed. This highly toxic form of mercury produces corrosive bronchitis and

interstitial pneumonia. All forms of mercury cross the placenta. Inorganic forms of mercury bind to sulfhydryl groups in enzymes and other thiol-containing molecules such as cysteine and glutathione. Tissues rich in these components, such as the renal cortex, accumulate significant concentrations of mercury. Inorganic forms of mercury are cytotoxic and highly corrosive. Consequently, these forms of mercury cause severe inflammation, ulcers, and direct tissue necrosis in the GI tract. Pale, swollen kidneys manifested histologically by tubular necrosis and interstitial nephritis are consistent findings.

Clinical Findings: The inhalation of corrosive elemental mercury vapors that produces severe dyspnea and compromised respiratory function is usually fatal at high levels of exposure. Neurologic manifestations may eventually develop if exposure is not excessive. Inorganic mercury, related to its corrosive nature, produces primarily GI manifestations, including colic, anorexia, stomatitis, pharyngitis, vomiting, diarrhea, shock, dyspnea, and dehydration. Death often occurs within hours at high levels of exposure. Animals that survive may exhibit eczema, skin keratinization, anuria, polydipsia, hematuria, or melena. Neurologic manifestations, including CNS depression or excitation similar to that which occurs in organic mercury poisoning, may develop after chronic exposure. Depending on the level of exposure to organic mercury compounds such as methylmercury, clinical manifestations may require days to develop. Because these compounds are not corrosive, GI signs are not seen. Neurologic manifestations that predominate include blindness, ataxia, incoordination, tremors, abnormal behavior, hypermetria, nystagmus (cats), and tonic-clonic convulsions. Advanced stages may be characterized by depression, anorexia, proprioceptive defects, total blindness, paralysis, and high mortality. The nervous system of young, developing animals is particularly susceptible to organic mercury exposure, which is frequently manifested by cerebellar ataxia and death.

Diagnosis: The considerable variation associated with the clinical manifestations

related to the form of mercury and the duration of exposure accentuates the need for multiple tissue analyses. Because inorganic forms of mercury are excreted in the urine, urinary mercury concentrations are the most reliable indicator of exposure. In contrast, organic mercury compounds, which bioaccumulate in soft tissues, are most appropriately assessed in the liver, kidney, or brain tissues. In most species, blood, kidney, brain, and feed concentrations of mercury <0.1 mg/kg (wet weight) are considered normal. In poisoned species, concentrations >6 mg/kg (blood), 10 mg/kg (kidney), 0.5 mg/kg (brain), and 4 mg/kg (feed, dry weight) are consistent with a diagnosis of mercury poisoning. Generally, the kidney is considered to be the most useful tissue diagnostically. Concentrations in all tissues may be substantially higher after chronic exposure. Marine mammals and fish often contain substantially increased concentrations of mercury that may not be associated with clinical disease (as such concentrations would be associated in traditional livestock or companion animal species), but they may be a potential source of exposure for more susceptible species, particularly the fetus or younger animals. Other measurements, including the presence of proteinuria, azotemia, or a nonregenerative anemia, may provide useful evidence to support a diagnosis of mercury poisoning. The diagnosis may be made on the basis of tissue analysis in association with appropriate histopathology, clinical pathology, clinical manifestations, and history. Differential diagnoses may include conditions that produce GI disturbances,

renal disease, or neurologic dysfunction manifested by tremors, ataxia, or convulsions. Metals such as lead, arsenic, thallium, or cadmium; insecticides, including organophosphate, carbamate, or organochlorine compounds; oxalates; vitamin D; or mycotoxins such as T-2 toxin should be considered. Infectious diseases, including hog cholera, erysipelas, and feline parvovirus, may resemble mercury poisoning.

Treatment and Control: Because the neurologic and renal damage is irreversible, treatment alternatives may be ineffective. Consequently, the prognosis for a complete recovery is very poor. In food-producing animals, significant mercury accumulation in edible tissues and profound effects on reproduction limit treatment options. Euthanasia and disposal, in consultation with regulatory officials, is recommended. Oral administration of activated charcoal (1–3 g/kg) and sodium thiosulfate (0.5–1 g/kg) will bind mercury and limit absorption. Vitamin E and selenium, which are antioxidants, may limit oxidative damage. Chelation therapy may be useful if treatment is started soon after exposure before nephrotoxic effects become severe. The lipid-soluble chelator dimercaprol (3 mg/kg body wt, IM, every 4 hr for 2 days, followed by qid treatment on day 3 and bid treatment for 10 days) may be beneficial. For organic mercury poisoning, 2,3-dimercaptosuccinic acid (10 mg/kg, PO, tid for 10 days) has been useful in dogs. If the GI tract has been decontaminated for mercury, administration of penicillamine (50–100 mg/kg/day, PO, for 2 wk) may reduce clinical signs.

MOLYBDENUM POISONING

Molybdenum is an essential element associated with a variety of metalloenzymes and corresponding metabolic functions. Excessive dietary intake of molybdenum induces a secondary copper deficiency. The syndrome, predominately reported in ruminants (versus nonruminant species) is seen worldwide. Cattle and sheep are ~10-fold more susceptible than other species. Acute toxicity associated with massive doses is rarely encountered.

Etiology: The interactions associated with copper, molybdenum, and sulfate

metabolism related to the utilization, bioavailability, and kinetics of copper are among the most biologically significant interrelationships in veterinary medicine. The complexity of the interactions is not fully understood. In ruminants, various molybdates react with sulfides to produce thiomolybdate compounds, which react with copper to form an insoluble complex that is poorly absorbed. The reduced copper absorption impairs copper utilization and the synthesis of a variety of copper-dependent proteins. The reduced bioavailability of copper ultimately induces secondary

copper deficiency. Excessive molybdenum intake also enhances the excretion of copper. Based on this observation, the administration of tetrathiomolybdates may be a useful treatment for chronic copper poisoning (see p 3073). The limited bacterial formation of thiomolybdates in monogastric animals is primarily responsible for the tolerance to molybdenum encountered in these species. Excessive molybdenum exposure may also impair a variety of enzymes involved in collagen and elastin maintenance and stability, which has been associated with cardiovascular disorders. Molybdenum exposure may reduce phospholipid synthesis in nervous tissue, resulting in demyelination and neurologic disorders clinically.

The susceptibility to molybdenum toxicity in ruminants depends on a number of factors, including 1) dietary copper content—susceptibility increases as the copper content decreases; 2) dietary sulfate content—susceptibility increases with high sulfate levels by impairing copper utilization, whereas low sulfate content enhances susceptibility by reducing molybdenum excretion; 3) the chemical form of molybdenum—water-soluble forms found in fresh feed are more toxic; 4) sulfur-containing amino acids may alter copper utilization or molybdenum excretion; 5) animal species—cattle are more susceptible; 6) age—young animals are more susceptible, and excretion of molybdenum into milk may produce toxicoses in nursing calves; 7) season of year—molybdenum concentrations in plants increase in the fall; 8) plant species—legumes bioaccumulate more molybdenum; and 9) breed differences—seen in sheep and goats.

Molybdenum toxicity has been encountered in regions of the world containing peat, muck, or shale soil types that are naturally contaminated with molybdenum. Industrial contamination associated with mining or metal production or areas using molybdenum-contaminated fertilizers result in enhanced uptake of molybdenum by plants used as a feed source.

Clinical Findings: The manifestations of molybdenum toxicity are related primarily to impaired copper metabolism and utilization, resulting in secondary copper deficiency. Typically, the syndrome is a herd problem, with morbidity as high as 80%. In cattle, clinical disease is characterized by severe, persistent diarrhea with the presence of green, liquid feces containing gas bubbles, often referred to as peat or teart scours. Depigmentation, resulting in fading achromotrichia of the hair coat, is

evident in black animals associated with impaired tyrosinase activity and reduced melanin synthesis. Pica, unthriftiness, microcytic hypochromic anemia, emaciation, joint pain characterized by lameness, and osteoporosis often manifested by bone fractures are seen. Molybdenum competes with phosphorus utilization, resulting in reduced mineralization of bone. In heifers, fertility is reduced. Delayed puberty, poor conception rates, decreased weight at puberty, and decreased milk production are common. Reduced libido has been reported in bulls. In sheep, particularly in lambs <30 days old, the animals exhibit stiffness of the back and legs and have difficulty rising. The syndrome in sheep is known as enzootic ataxia, or swayback. Abnormal development of connective tissue and growth plates are apparent in affected animals. Manifestations appear within 1–2 wk if molybdenum levels are excessive.

Occasionally, acute toxicity may be encountered in cattle or sheep. Anorexia and lethargy may be evident within 3 days. Deaths begin within 1 wk and may continue for many months. Neonates frequently exhibit hindlimb ataxia that often progresses to the forelimbs. Salivation and scant mucoid feces are common.

At necropsy, hemosiderosis, periarterial severe hepatic necrosis, and nephrosis are evident. In affected sheep, neuronal degeneration, demyelination, and lysis of white matter are seen in nervous tissue.

Diagnosis: Distinguishing between primary copper deficiency and secondary copper deficiency related to excessive molybdenum exposure is important. Often with molybdenum toxicity, there is a poor correlation between tissue concentrations of copper and clinical disease. Clinical improvement after copper sulfate administration provides valuable support for the diagnosis. Analysis of the ration for copper and molybdenum concentrations is recommended. In cattle rations, a copper:molybdenum ratio of 6:1 is optimal. If the ratio is less than 2:1, molybdenum toxicity will occur. Ratios exceeding 15:1 may cause chronic copper poisoning. Absolute molybdenum concentrations in the diet >10 mg/kg will cause poisoning independent of copper consumption. Massive molybdenum exposure in the ration >2,000 mg/kg will result in death. Analysis of the liver and plasma for molybdenum provides useful insight to confirm the diagnosis, but the concentrations must be interpreted in association with the comparable tissue concentrations

of copper. In cattle, liver concentrations >2 ppm (wet weight) and plasma concentrations >0.1 ppm are consistent with a diagnosis of molybdenum poisoning in the presence of a low copper status. Other disease syndromes characterized by emaciation or unthriftiness (parasite infections, selenosis, fluorosis, ergotism), diarrhea (metal poisonings, GI infections), and lameness or bone abnormalities (fluorosis, selenosis, ergotism, lead poisoning) may resemble molybdenum poisoning and should be investigated as possible etiologies.

Treatment and Prevention: Most treatment options are associated with the biological interactions associated with copper, molybdenum, and sulfate. Under circumstances in which dietary exposure is difficult to eliminate, simple treatment with copper products may be futile. If the source of molybdenum can be removed, excess

molybdenum is rapidly eliminated and food products are safe for consumption within a relatively short time. If the dietary exposure cannot be reduced, elimination of molybdenum in the milk may produce toxicosis in nursing calves. Dietary supplementation with copper sulfate will reduce the bioavailability of molybdenum in the GI tract, ultimately reducing absorption and enhancing excretion. In feed containing molybdenum at >5 mg/kg, supplementation with 1% copper sulfate in salt will control development of the syndrome. In recovered mining areas, the supplementation may need to be increased to as much as 5% copper sulfate in the salt. When the consumption of mineral supplements is impractical, the treatment may be administered as a weekly drench. Injectable products such as copper glycinate or copper edetate (Cu-EDTA) may be given at a dose of 120 mg/cow. These products are approved only in some jurisdictions.

SALT TOXICITY

Excessive salt (sodium chloride, NaCl) intake can lead to the condition known as salt poisoning, salt toxicity, hypernatremia, or water deprivation–sodium ion intoxication. The last term is the most descriptive, giving the result (sodium ion intoxication) as well as the most common predisposing factor (water deprivation.) Salt poisoning is unlikely to occur as long as sodium-regulating mechanisms are intact and fresh drinking water is available.

Salt poisoning has been reported in virtually all species of animals all over the world. Although salt poisoning has historically been more common in swine (the most sensitive species), cattle, and poultry, there are increasing reports of adverse effects in dogs from acute excess salt consumption. The acute oral lethal dose of salt in swine, horses, and cattle is ~ 2.2 g/kg; in dogs, it is ~ 4 g/kg. Sheep appear to be the most resistant species, with an acute oral lethal dose of 6 g/kg.

Etiology: In general, animals can tolerate high concentrations of salt or sodium in the diet if they have continuous access to fresh water. Salt poisoning is often directly related to water consumption and can be reduced

significantly or abolished completely by appropriate management of factors such as mechanical failure of waterers, overcrowding, unpalatable medicated water, new surroundings, or frozen water sources. Both swine and poultry on normal diets can be severely affected when water intake is completely restricted or when consuming high-salt diets with moderate water restriction. Increased water requirements increase the susceptibility of lactating cows and sows to salt poisoning, especially in response to sudden restrictions in water.

High concentrations of salt in the diet (up to 13%) have been used to limit feed intake of cattle. Salt-deprived animals or those not acclimated to high-salt diets can overconsume these feeds, making the animals prone to salt poisoning. Improperly formulated or mixed feed can be sources of excess salt. The use of whey as a feed or as a component of wet mash can add to sodium intake. Additional sources of excess sodium can include high-saline ground water, brine, or seawater.

Chickens can tolerate up to 0.25% salt in drinking water but are susceptible to salt poisoning when water intake is restricted. Wet mash containing 2% salt has caused salt

poisoning in ducklings. High salt content in wet mash is more likely to cause poisoning than in dry feed, probably because birds eat more wet mash.

Sheep can tolerate 1% salt in drinking water; however, 1.5% may be toxic. It is generally recommended that drinking water contain <0.5% total salt for all species of livestock.

Companion animal exposures to excess salt have included the use of salt as an emetic (no longer recommended) and the ingestion of various salt-containing materials including rock salt and dough-salt mixtures. Dogs have been reported to develop hyponatremia after swimming/playing in the ocean (which contains 3.5% sodium) without having access to fresh water. Horses appear to be rarely affected with classic salt poisoning but can develop it under conditions of increased salt intake and sudden water restriction.

Clinical Findings: In pigs, early signs (rarely seen) may be increased thirst, pruritus, and constipation. Affected pigs may be blind, deaf, and oblivious to their surroundings; they will not eat, drink, or respond to external stimuli. They may wander aimlessly, bump into objects, circle, or pivot around a single limb. After 1–5 days of limited water intake, intermittent seizures occur with the pig sitting on its haunches, jerking its head backward and upward, and finally falling on its side in clonic-tonic seizures and opisthotonos. Terminally, pigs may lie on their sides, paddling in a coma, and die within a few to 48 hr.

In cattle, signs of acute salt poisoning involve the GI tract and CNS. Salivation, increased thirst, vomiting (regurgitation), abdominal pain, and diarrhea are followed by ataxia, circling, blindness, seizures, and partial paralysis. Cattle sometimes manifest belligerent and aggressive behavior. A sequelae of salt poisoning in cattle is dragging of hindfeet while walking or, in more severe cases, knuckling of the fetlock joint.

In poultry and other birds, clinical signs include increased thirst, dyspnea, fluid discharge from the beak, weakness, diarrhea, and leg paralysis.

Excess salt intake in dogs results in vomiting within several hours of ingestion. The clinical signs can progress to weakness, diarrhea, muscle tremors, and seizures.

Lesions: Postmortem examination may reveal some degree of gastric irritation, including ulceration and hemorrhages. The content of the GI tract may be abnormally dry. Histopathologic lesions may be limited to the brain and include cerebral edema and

inflammation of the meninges. During the first 48 hr, swine develop eosinopenia, eosinophilic cuffs around vessels in the cerebral cortex and adjacent meninges, and cerebral edema or necrosis. After 3–4 days, eosinophilic cuffs are usually no longer present. Cattle do not develop eosinophilic cuffs but can have edema of the skeletal muscles as well as hydropericardium. Chickens can also have hydropericardium.

In acute cases, no gross lesions may be present in any species.

Diagnosis: Serum and CSF concentrations of sodium >160 mEq/L, especially when CSF has a greater sodium concentration than serum, indicate salt poisoning. Brain sodium concentrations >2,000 ppm (wet weight) are considered diagnostic in cattle and swine. There is a lack of data on normal brain sodium concentrations in other common domestic species, making interpretations of brain sodium concentrations difficult. Characteristic history and clinical signs, along with clinical pathology, postmortem findings, and analyses of feed or water for sodium content are essential for establishing a diagnosis.

In swine, differential diagnoses include insecticide poisoning (organochlorine, organophosphorus, and carbamate), phenylarsonic poisoning, and pseudorabies. In cattle, differential diagnoses include insecticide and lead poisoning, polioencephalomalacia, hypomagnesemic tetany, and the nervous form of ketosis.

Treatment: There is no specific treatment for salt poisoning. Immediate removal of offending feed or water is imperative. Fresh water must be provided to all animals, initially in small amounts at frequent intervals to avoid exacerbation of clinical signs. On a herd basis with large animals, water intake should be limited to 0.5% of body weight at hourly intervals until normal hydration is accomplished, usually taking several days. Severely affected animals can be given water via stomach tube. The mortality rate may be >50% in affected animals regardless of treatment. In small animals before the onset of clinical signs, the acute ingestion of salt can best be treated by allowing the animal access to water and closely observing it for several hours. Emetics may be used in dogs if known ingestions occur and the dog is not yet showing clinical signs.

For all affected animals, the treatment should slowly return the animal to normal water and electrolyte balance over 2–3 days. Quickly lowering the serum sodium concentration will increase the osmotic

gradient between the serum and the brain, with water following the gradient into the brain and increasing the likelihood of severe cerebral edema.

Monitoring serum sodium concentration is the first step in treating individual animals. Serum sodium levels should be lowered at a rate of 0.5–1 mEq/L/hr. The use of slightly hypertonic IV fluids has been recommended to reduce the likelihood of cerebral edema.

IV fluids can be made to approximate the serum sodium concentration of the animal, or a solution containing sodium at 170 mEq/L can be used initially, with the concentration decreased as clinical signs improve. In dogs, a series of warm water enemas given at intervals of several hours has helped reduce acutely increased sodium levels. If brain edema is suspected, mannitol, dexamethasone, or DMSO may be helpful.

SELENIUM TOXICOSIS

Selenium is an essential element that has a narrow margin of safety, with the difference between adequate and potentially toxic concentrations in the diet being approximately 10- to 20-fold. Feed supplements, resulting in final selenium content of 0.2–0.3 ppm, are added to diets to prevent deficiency and resultant diseases such as white muscle disease in cattle and sheep, exertional myopathy in horses, hepatosis dietetica in pigs, and exudative diathesis in chickens. The maximum tolerable concentrations for selenium in most livestock feed is considered to be 2–5 ppm, although some believe 4–5 ppm can inhibit growth.

Selenium is an essential component of >25 selenoenzymes and selenoproteins. The most recognized of these are the glutathione peroxidase enzymes that act as antioxidants in the body. In excess, selenium potentially has three general toxic effects: the direct inhibition of cellular oxidation/reduction reactions by depleting glutathione and S-adenosylmethionine reserves, the production of free radicals that cause oxidative tissue damage, and the replacement of sulfur/sulfur-containing amino acids in the body with selenium/seleno-amino acids. The inhibition of numerous cellular functions by high concentrations of selenium results in acute generalized cytotoxicity. The replacement of sulfur-containing amino acids with seleno-amino acids leads to altered structure and function of cellular components and enzymes due to loss of the disulfide bonds that commonly occur between sulfur-containing amino acids. Loss of these disulfide bonds can alter the three-dimensional configuration of proteins, potentially resulting in loss of or diminished enzyme activity. The most commonly altered sulfur-containing amino acids are methionine and cysteine, which

are replaced with selenomethionine and selenocysteine, respectively. Replacement of these amino acids with selenium-containing amino acids also affects cell division and growth. Especially susceptible are the cells that form keratin (keratinocytes) and the sulfur-containing keratin molecule. Selenium therefore weakens the hooves and hair, which tend to fracture when subjected to mechanical stress.

Etiology: All animal species are susceptible to selenium toxicosis. However, poisoning is more common in forage-eating animals such as cattle, sheep, horses, and other herbivores that may graze selenium-containing plants. Plants may accumulate selenium when the element is found at high concentrations in the soil, but pH and moisture content of the soil play roles in the relative bioavailability of selenium to plants. Generally, selenium is most bioavailable to plants when they grow on more alkaline soils with low rainfall (<50 cm). The alkalinity and low moisture content of the soil tend to allow more of the selenium to be retained as the oxidized form of selenate, which is the most readily available for plant uptake. Because low moisture in the soil decreases the anaerobic environments to greater depths, drought conditions could allow for more/deeper selenium in the soil to be oxidized into plant-available forms, resulting in year-to-year variability in available selenium for plant uptake.

Selenium-accumulating plants have been categorized based on their relative requirements and ability to accumulate selenium. Obligate indicator plants require large amounts of selenium for growth and contain high selenium concentrations (often >1,000 to 10,000 ppm). Obligate indicators include species of *Astragalus*, *Stanleya*,

Machaeranthera, *Oenopsis*, and *Xylorhiza*. Facultative indicator plants absorb and tolerate higher concentrations of soil selenium, with accumulations ranging from trace amounts to a few thousand ppm, but they do not require selenium for growth. Facultative indicators include species of *Aster*, *Castilleja*, *Grindelia*, *Atriplex*, *Gutierrezia*, and *Comandra*. Nonaccumulator plants, such as most grasses, passively absorb much lower amounts of selenium from the soil, resulting in trace amounts to a few hundred ppm.

Numerous organic and inorganic chemical forms of selenium are potentially present in plants. Nonaccumulator plants primarily contain selenomethionine, while indicator plants contain more selenate and methylselenocysteine. In comparison, most supplemental dietary sources are in the form of selenite, but selenomethionine supplements are becoming more commonly used in marketed products.

Poisoning may also occur in swine, poultry, and other species consuming grain raised on seleniferous soils or, more commonly, due to errors in feed formulation. Selenium toxicosis after ingestion of selenium-containing shampoos or selenium supplement tablets is rare in small animal pets but can occur. Several factors are known to alter selenium toxicity; however, in general, a single acute oral dose of selenium in the range of 1–10 mg/kg may be lethal in most animals. Parenteral selenium products are also quite toxic, especially to young animals, and have caused deaths in piglets, calves, lambs, and dogs at dosages as low as 1 mg/kg. Younger animals tend to be more susceptible to selenium poisoning, and the chemical forms can result in some differences in relative toxicity.

Diagnosis: Severity of clinical signs of selenium toxicosis depends on the quantity and duration of exposure. Poisoning in animals is characterized as acute, subchronic, or chronic. Diagnosis is based on clinical signs, necropsy findings, and laboratory confirmation of the presence of high selenium content in an animal's diet (feed, forage, grains, or water), serum, blood, or tissues (eg, kidney, liver). Selenium in the diet at >5 ppm may produce mild clinical effects after prolonged exposure of ≥30 days. Concentrations of 10–25 ppm would be expected to produce severe clinical signs with prolonged exposure. Environmental exposure potential should be based on forage, feed, or water content, not on soil selenium content, because some chemical forms in soil are not

available for uptake by plants and would not result in high exposure potential.

Tissue selenium content is the basis for diagnosing selenium poisoning in animals. Organic chemical forms of selenium have greater bioavailability and are retained in the tissues for much longer periods. Thus, timing of the exposure in relation to the collection of tissue, blood, or serum, as well as the chemical form of the selenium exposure, must be taken into account when interpreting the selenium content. In addition, some species variability in regard to concentrations also occurs. In acute toxicosis, the blood and serum selenium concentrations are generally >3–4 ppm, and in chronic toxicosis, it is generally >1–2 ppm. Liver generally contains >3–5 ppm selenium in acute cases, whereas in chronic cases it should be >1.5 ppm. Kidney of selenium-poisoned animals generally contains >1–5 ppm. Hair and hoof wall may have >1.5–5 ppm selenium in chronic poisoning. A "garlicky" odor on the animal's breath may be noted; this finding is more prominent with acute poisoning but can be seen with chronic poisoning as well. The odor is due to elimination pathways producing methylated selenium metabolites that are volatile and expired but may last for only 1–2 days after an acute poisoning incident.

CHRONIC SELENIUM TOXICOSIS

(Alkali disease)

Chronic selenium poisoning usually develops when livestock consume seleniferous forages and grains containing 5–50 ppm of selenium for many weeks or months, although chronic exposure to high concentrations of inorganic selenium can also produce chronic selenosis. Naturally occurring seleno-amino acids in plants are readily absorbed and inserted into proteins in place of their corresponding sulfur-containing amino acids (ie, selenomethionine in place of methionine or selenocysteine in place of cysteine). Until recently, two types of chronic selenium poisoning were discussed in the literature: alkali disease and blind staggers. Blind staggers is no longer believed to be caused by selenium but by sulfate toxicity due to consumption of high-sulfate alkali water and/or high sulfur-containing forages. Excess sulfate (>1% of diet) leads to polioencephalomalacia and the classical signs of blind staggers. Animals consuming milk vetch (*Astragalus bisulcatus*) have demonstrated clinical signs similar to those of blind staggers. Although milk vetch contains high levels of selenium, evidence now indicates that the

alkaloid swainsonine in milk vetch is responsible for locoism and produces the neurologic clinical signs.

Clinical Findings: Alkali disease has been reported in cattle, sheep, and horses. Affected animals are inactive, weak, anorexic, lame, emaciated, anemic, and lack vitality. In addition, the most distinctive lesions are those produced by damage of the keratin of the hair and hooves. For horses, the predominant clinical manifestation is lameness due to founder. The animal has a rough hair coat, and the long hairs of the mane and tail break off, giving a "bob" tail and "roached" mane appearance. Abnormal growth and structure of horns and hooves result in circular ridges and cracking of the hoof wall at the coronary band. Extremely long, deformed hooves that turn upward at the ends also may be seen. Subsequent lameness is compounded by degeneration of joint cartilage and bone. Reduced fertility and reproductive performance occurs, especially in sheep and cattle. Reproductive performance may be impaired with a dietary selenium content lower than that required to produce the other typical signs of alkali disease. Other lesions may include liver cirrhosis, ascites, and myocardial necrosis/scarring.

Birds also may be affected with chronic selenium toxicosis. Eggs with >2.5 ppm selenium from birds in high selenium areas have low hatchability and embryos that are usually deformed. Teratologic effects include underdeveloped feet and legs, malformed eyes, crooked beaks, and rupy feathers. This has been a problem with waterfowl in southern California, where selenium was concentrated in lakes by runoff.

In selenium-poisoned animals, some alterations in blood chemistries occur. These changes include decreased prothrombin activity, fibrinogen, and glutathione, as well as increased serum alkaline phosphatase, ALT, AST, and succinic dehydrogenase.

Treatment and Control: There is no specific treatment for selenium toxicosis. Eliminating the source and exposure, as well as symptomatic and supportive care of the animal, should be started as soon as possible. Addition of substances that antagonize or inhibit the toxic effects of selenium in the diet may help reduce the risk of selenium toxicosis. A high-protein diet, linseed oil meal, sulfur, arsenic, silver, copper, cadmium, and mercury have reduced selenium toxicity in laboratory animals, but their use under field conditions is limited. However, some of the poor

reproductive performance associated with selenium poisoning can be decreased by copper supplementation. Addition of arsenic salt at 0.00375% to enhance biliary excretion of selenium or a high-protein diet to bind free selenium has historically been used to reduce incidence of selenium poisoning in cattle. However, this has minimal to poor overall efficacy. Chronically selenium-poisoned animals are less likely to thrive than herdmates, even after exposure has been stopped.

Forages should be tested regularly in high-selenium areas to evaluate year-to-year risk.

SUBCHRONIC SELENIUM TOXICOSIS

Pigs fed a diet supplemented with selenium >20–50 ppm for >3 days develop a subchronic selenium toxicosis characterized by neurologic abnormalities. Animals are initially ataxic and uncoordinated, followed by anterior paresis, then quadriplegia. Even though neurologic impairment is occurring, the pigs continue to eat, which would indicate neurologic damage that is not centrally mediated. The hooves show breaks and impaired growth similar to those seen in cattle. Alopecia may also be seen. In sows, conception rate decreases and the number of stillborn pigs increases. Lesions of subchronic toxicosis include focal symmetric polymyelomalacia, which is most prominent in the cervical and thoracic spinal cord. Death may result from complications of permanent paralysis. Hoof and hair damage is similar to but in most cases less severe than that seen in chronic selenium toxicosis. Treatment is similar to that for chronic toxicosis, but spinal lesions are usually permanent.

ACUTE SELENIUM TOXICOSIS

Acute oral selenium poisoning due to consumption of plants or mis-mixed diets with concentrations >50 ppm (dosages 1–10 mg/kg or greater, depending on the species, age, and chemical form of selenium) is not common but has caused large losses in cattle, sheep, and pigs. Animals usually avoid plants with high selenium content because of their offensive odor; however, when pasture is limited, accumulator plants may be the only food available. In some cases, plants may not have the profound offensive odor. Young animals are most susceptible to acute parenteral selenium toxicosis with dosages of 0.2–0.5 mg/kg. Clinical signs are

different from those of chronic selenosis and are characterized by abnormal behavior, respiratory difficulty, GI upset, and sudden death. Abnormal posture and depression, anorexia, unsteady gait, diarrhea, colic, increased pulse and respiration rates, frothy nasal discharge, moist rales, and cyanosis may be noted. Sheep usually show these signs to a much lesser degree or just become depressed and die suddenly.

Most deaths usually follow within a few hours to 2 days after an acutely toxic

consumption or injection of selenium. The major lesions are pulmonary edema, pulmonary congestion, pulmonary hemorrhage, hepatic necrosis, myocardial necrosis, myocardial hemorrhage, and potentially renal necrosis.

Blood or serum selenium concentration in acute poisoning is often higher than in chronic poisoning. Treatment consists of symptomatic and supportive care. Acetylcysteine to boost systemic glutathione concentrations may be beneficial.

ZINC TOXICOSIS

Zinc is an essential trace metal that plays an important role in many of the body's enzymatic processes. It is ubiquitous in nature and exists in many forms. The ingestion of some forms of zinc causes the creation of toxic zinc salts in the acidic environment of the stomach. Zinc toxicity has been documented in people as well as in a wide range of large, small, exotic, and wild animals. Exposure typically stems from dietary indiscretion. Household sources of zinc include paint, batteries, automotive parts, zinc oxide creams, vitamin and mineral supplements, zipper pulls, board-game pieces, pet carrier screws and nuts, and the coating on certain types of pipes and cookware. ● One of the most well-known sources of zinc that causes toxicity after ingestion is the USA Lincoln penny. Some pennies minted during 1983, and all pennies minted since, are 97.5% zinc by weight (~2,440 mg of elemental zinc per coin).

Pathogenesis: The low pH in the stomach causes the release of free zinc, which then forms soluble, caustic zinc salts. These salts are absorbed from the duodenum and rapidly distributed to the liver, kidneys, prostate, muscles, bones, and pancreas. Zinc salts have direct irritant and corrosive effects on tissue, interfere with the metabolism of other ions such as copper, calcium, and iron, and inhibit erythrocyte production and function. The mechanisms by which zinc exerts these toxic effects are not completely understood. The LD₅₀ of zinc salts in cases of acute toxicity has been reported to be ~100 mg/kg. Also, diets containing high levels of zinc (>2,000 ppm) have been reported to cause chronic zinc toxicosis in large animals.

Clinical Findings and Lesions: Clinical signs vary based on the duration and degree of exposure. Signs progress from anorexia, vomiting, diarrhea, and lethargy to more advanced signs such as intravascular hemolysis, icterus, hemoglobinuria, cardiac arrhythmias, and seizures. Large animals often show decreases in weight gain and milk production, and lameness has been reported in foals secondary to epiphyseal swelling.

Major histopathologic findings include hepatocellular centrilobular necrosis with hemosiderosis and vacuolar degeneration, renal tubular necrosis with hemoglobin casts, and pancreatic duct necrosis with fibrosis of the interlobular fat.

Diagnosis: Radiodense foreign bodies are easily seen on radiographs of the GI tract and should raise suspicion of potential zinc toxicosis in animals with correlating clinical signs. Changes in the CBC, chemistry profile, urinalysis, and coagulation profile reflect the degree of toxicity to various organ systems. The hemogram can reveal anemia characterized by changes in erythrocyte morphology such as spherocytosis and Heinz body formation. (It has been suggested that zinc's interference with enzymes such as glutathione reductase leads to erythrocyte fragility due to oxidative damage.) The leukogram often shows a mature neutrophilic leukocytosis secondary to stress, pancreatitis, and a regenerative response by the bone marrow. Serum chemistry changes that are seen secondary to hepatic damage include increases in bilirubin, the transaminases, and alkaline phosphatase.

As zinc accumulates in the pancreas, increases in amylase and lipase can be seen following pancreatitis and pancreatic

necrosis. Glomerular damage and renal tubular epithelial necrosis result in increases in BUN, creatinine, amylase, and urine protein. Hemoglobinuria can be differentiated from hematuria during urinalysis; the urine color will not clear after centrifugation in the presence of hemoglobinuria. Prolongation of prothrombin time and activated partial thromboplastin time can also result from toxic effects on the synthesis or function of coagulation factors and the loss of clotting proteins through the glomerulus of the kidneys.

The hematologic and clinical findings in animals with zinc toxicosis are similar to the changes in animals with immune-mediated hemolytic anemia (IMHA). Zinc toxicosis can cause the direct antiglobulin test (direct Coombs' test) to be positive in the absence of a primary autoimmune disorder, so the direct Coombs' test is not a reliable method to differentiate zinc intoxication from IMHA.

Zinc levels can be measured in blood to confirm toxicosis, although this is usually unnecessary to diagnose zinc poisoning in the clinical setting. In dogs and cats, the normal serum zinc level is 0.7–2 mcg/mL. Reference laboratories usually request that samples be submitted in green-top heparinized tubes, royal blue-top trace element tubes, or purple-top EDTA tubes. Methods to quantify zinc levels from saliva and hair have not been validated in domestic animals, and measuring zinc in urine is unreliable because elimination of zinc through the kidneys is variable.

Treatment and Prevention: After stabilizing the animal with fluids, oxygen, and blood products as necessary, removal of the source of zinc as early as possible is paramount. This often requires surgery or endoscopy. Inducing emesis to remove chronic gastric zinc foreign bodies may be

tried within the first hour or two of exposure but may not be rewarding in advanced cases because zinc objects can adhere to the gastric mucosa.

Proton pump inhibitors and H_2 -blockers can be used to decrease the formation of zinc salts in the stomach before removal of the source of zinc, and gastroprotectant therapy with sucralfate can later be considered to help address gastric ulceration.

Diuresis with a balanced crystalloid solution is indicated to promote renal excretion of zinc and prevent hemoglobinuric nephrosis.

There is debate regarding the necessity of chelation therapy in cases of zinc toxicosis. Animals often recover from zinc intoxication after only supportive care and removal of the source. Chelation therapy can enhance elimination of zinc and thus accelerate recovery, but there is some concern that chelation treatment may actually increase zinc absorption from the intestines. Chelation can be achieved through the use of specific compounds. Ca-EDTA chelates zinc when given at 100 mg/kg/day, IV or SC, for 3 days (diluted and divided into four doses) but may exacerbate zinc-induced nephrotoxicity. Although they have been used to treat animals with zinc toxicity, n-penicillamine and dimercaprol (British anti-lewisite) have not been specifically validated for this purpose. Reported dosages are 110 mg/kg/day for 7–14 days for n-penicillamine, and 3–6 mg/kg, tid, for 3–5 days for dimercaprol. Chelation therapy with any of these agents should be performed only after careful consideration and should be monitored with serial serum zinc levels to help determine the appropriate duration of treatment.

With early diagnosis and treatment, the outcome is usually favorable for animals with zinc toxicosis. Eliminating exposure to zinc in the environment is essential to prevent recurrence.

BRACKEN FERN POISONING

Bracken fern (*Pteridium aquilinum*) is found throughout the world and is among the five most numerous vascular plants. The species includes numerous subspecies and varieties, and plant size varies with frond lengths of 0.5–4.5 m. Bracken fern is perennial, with erect deciduous fronds that remain green until they are

killed by frost or drought. It spreads primarily through dense rhizome networks and can dominate plant communities, especially those burned or disturbed. Bracken fern may be found in a diversity of sites but is most common in semishaded, well-drained, open woodlands.

Bracken fern (*Pteridium aquilinum*), growing from large dense woody rhizomes, forms deciduous, stipitate, erect to spreading fronds with nonanastomosing veins. The pinnae are stalked, opposite or subopposite (inset). Courtesy of Dr. Bryan Stegelmeier.

Syndromes: A variety of syndromes have been associated with bracken fern poisoning. These syndromes are largely determined by the dose and duration, and also by the species of the poisoned animal.

Enzootic Hematuria: Enzootic hematuria is the most common result of bracken fern poisoning. It primarily affects cattle and, less frequently, sheep. It is characterized by intermittent hematuria and anemia. Poisoning most often occurs during late summer when other feed is scarce, or when animals are fed hay containing bracken fern. Poisoning requires prolonged exposures; affected livestock must ingest bracken fern for several weeks to years before disease develops.

Affected cattle are weak, rapidly lose weight, and develop pyrexia (106° – 110° F [41° – 43° C]) once clinical effects manifest. Calves often have difficulty breathing, with pale mucous membranes. Hemorrhages vary from minor mucosal petechia to effusive bleeding, and at times large blood clots form that may be passed in the feces. Coagulation is prolonged, and bleeding may be pronounced and excessive even at small wounds such as small insect bites or minor scratches.

Once animals develop clinical disease, poisoning is almost always fatal. Postmortem examinations usually reveal multiple hemorrhages or bruises throughout the carcass. Necrotic ulcers in the GI tract may be noted. The bladder mucosa often contains small hemorrhages; dilated vessels; or vascular, fibrous, or epithelial neoplasms. Other neoplasms in the upper GI tract of cattle and other species have also been reported. In most cases, mixtures of hemorrhagic and neoplastic lesions are found.

Although not all bracken fern toxins have been completely characterized, the

primary cause of enzootic hematuria has been attributed to norsesquiterpene glycosides (ptaquiloside, ptesculentoside, and caudatoside). Ptaquiloside is a potent radiomimetic that initially damages the bone marrow and later is carcinogenic (producing urinary tract neoplasia in ruminants). Both the hemorrhagic syndrome and uroepithelial neoplasms have been reproduced experimentally with bracken fern and ptaquiloside. Although less well characterized, the other norsesquiterpene glycosides, which predominate in some bracken fern populations, probably have similar toxicity and carcinogenicity.

Acute Brackenism (Hemorrhagic Disease): Acute brackenism occurs when animals ingest high doses over relatively short durations of weeks or months. It is characterized by bleeding. This toxicity is attributed to ptaquiloside's radiomimetic damage to proliferating bone marrow stem cells. This is seen as depletion of bone marrow megakaryocytes followed by panhypoplasia. The leukogram often shows a mixed response. In the initial phases, monocytosis may be pronounced and followed by granulocytopenia and thrombocytopenia. Final phases include marked thrombocytopenia with anemia, leukopenia, and hypergammaglobulinemia. Urinalysis generally shows hematuria and proteinuria. Affected animals have both an increased susceptibility to infection and a tendency for spontaneous hemorrhage.

Lower doses of bracken fern for longer duration are more likely to be carcinogenic. The effects seem cumulative, as animals are exposed repeatedly for years. Often the onset of clinical disease can be delayed for weeks, or even months, after animals have been removed from bracken fern-infested ranges and pastures. The carcinogenic potential of bracken fern and ptaquiloside has been confirmed not only in livestock but also in rats, mice, guinea pigs, quail, and Egyptian toads.

Ptaquiloside is excreted in the urine and milk, and small amounts have also been identified in skeletal muscle and liver of poisoned animals even after a 15-day withdrawal period. Contaminated milk retains toxicity; it has been shown to produce GI neoplasms in rats. Several investigators have suggested ptaquiloside neoplastic transformation may be promoted or enhanced by bovine papillomavirus infection. However, this may be a secondary change due to bracken fern–associated myelodysplasia and subsequent immunosuppression that are likely to promote papillomavirus infection.

Bright Blindness: A less common manifestation of ptaquiloside toxicity is called bright blindness. It is seen clinically as tapetal hyperreflectivity that is most commonly reported in sheep in parts of England and Wales. Affected sheep are permanently blind and adopt a characteristic alert attitude. The pupils respond poorly to light, and ophthalmoscopic examination of sheep with advanced disease reveals narrowing of arteries and veins and a pale tapetum nigrum with fine cracks and spots of gray. Histologically, the lesion is seen as severe atrophy of the retinal rods, cones, and outer nuclear layer that is most pronounced in the tapetal portion of the retina. Affected animals often have many of the other bracken fern-associated lesions such as bone marrow suppression, hemorrhage, immunosuppression, and urinary tract neoplasia.

Bracken Stagers: Bracken fern poisoning in monogastric animals was first recognized as a neurologic disease when horses consumed contaminated hay. Ingestion at a rate of 20%–25% bracken fern for ≥3 mo may result in bracken stagers. Clinical signs in horses include anorexia, weight loss, incoordination, and a crouching stance while arching the back and neck with the feet placed wide apart. When the horse is forced to move, trembling muscles are noted. In severe cases, tachycardia and arrhythmias are present; death (usually 2–10 days after onset) is preceded by convulsions, clonic spasms, and opisthotonos. These changes are due to bracken fern thiaminases. The resulting disease is similar to vitamin B₁ deficiency, and therefore most animals respond to thiamine therapy. Horses seem to be particularly susceptible, whereas disease in pigs is rare. In pigs, the signs of thiamine deficiency are less distinct and may resemble heart failure. Affected pigs become anorectic and lose weight. Death can occur suddenly after recumbency and dyspnea. Thiamine deficiency is generally not a problem in ruminants, because the vitamin is synthesized in the rumen; however, polioencephalomalacia (see p 1281) associated with impaired thiamine metabolism in sheep has been attributed to consumption of bracken fern and rock or mulga fern (*Cheilanthes sieberi*) in Australia.

Treatment: Initial treatment for all species is to discontinue exposure to bracken fern; however, disease can appear weeks after livestock are removed from the fern-infested area. In acutely affected cattle,

mortality is usually >90%. Measurement of the platelet count is recommended, because it is the best prognostic indicator for poisoned animals.

Treatment of thiamine deficiency in horses is highly effective if diagnosis is made early. Injection of a thiamine solution at 5 mg/kg is suggested, given initially IV every 3 hr, then IM for several days. Oral supplementation may be required for an additional 1–2 wk, although SC injection of 100–200 mg/day for 6 days has been successful in some cases. Thiamine treatment should also include animals similarly exposed but not yet showing clinical disease, because signs can develop days or weeks after removal from the source of bracken.

Antibiotics may be useful to prevent secondary infections. Blood or even platelet transfusions may be appropriate but require large volumes (2–4 L blood) to effectively treat cattle. Though untested, treatment with granulocyte-macrophage colony-stimulating factor (used to treat aplastic anemia in people) may also be considered.

Prevention: Poisoning, apart from thiamine deficiency, is essentially untreatable; however, it is most easily controlled by preventing exposure. Bracken fern is usually grazed for want of alternative forages. Most commonly, animals are forced to eat bracken fern when other forage is exhausted in late summer, although some animals may develop a taste for the young tender shoots and leaves. Poisoning can be avoided by improving pasture management to increase production of alternative forage. It has been suggested that alternating bracken fern-contaminated and noncontaminated pastures at 3-wk intervals can minimize poisoning.

Bracken fern growth can be retarded by close grazing or trampling in alternative grazing pasture systems. Bracken fern density can be reduced by regular cutting of the mature plant or, if the land is suitable, by deep plowing. Herbicide treatment using asulam or glyphosate can be an effective method of control, especially if combined with cutting before treatment. Some bracken fern populations contain very low or no ptaquiloside. More work is needed to identify these populations, determine why they are not toxic, and use this information to predict or reduce toxicity.

Human Poisoning: Initial epidemiologic studies suggest that consumption of milk from cattle with access to bracken

increases risk of human esophageal or gastric cancer. Certainly the greater risk to people is direct consumption of bracken fern. Rhizomes have been used to make flour, and the young shoots or croziers are considered a delicacy in many parts of the world. Although preparing and cooking lessens the toxicity of ptaquiloside, it has been identified in these foods. Japanese scientists

have shown an association between consumption of bracken crozier and esophageal cancer. Additionally, ptaquiloside has been found as an environmental contaminant in soil and water, and airborne spores may also present a risk of human exposure. Human exposure through any means should be of concern, because ptaquiloside is a proven carcinogen.

GOSSYPOL POISONING

Gossypol poisoning, usually chronic, cumulative, and sometimes insidious, follows consumption of cottonseed or cottonseed products that contain excess free gossypol. It is of most concern in domestic livestock, especially preruminants or immature ruminants and pigs; mature ruminants are more resistant to gossypol's toxic effects. However, gossypol toxicosis can affect high-producing dairy cows with high feed intake, dairy goats, and other mature ruminants fed excess gossypol for long periods. It has also been reported in dogs fed cottonseed meal in diets or housed on cottonseed bedding.

Etiology: Gossypol, the predominant pigment and probably the major toxic ingredient in the cotton plant (*Gossypium* spp), and other polyphenolic pigments are contained within small, discrete structures called pigment glands found in various parts of the cotton plant. Gossypol is found in

cottonseed as both protein-bound and free forms; only the free form is toxic. Gossypol content of cottonseeds varies from a trace to >6% and is affected by plant species and variety and by environmental factors such as climate, soil type, and fertilization. Gossypol is a natural component of all but the rarely produced "glandless" variety of cotton.

Cottonseed is processed into edible oil, meal, linters (short fibers), and hulls. Cottonseed meal is marketed with 50%-90% protein, depending on intended use. Cottonseed and cottonseed meal are widely used as protein supplements in animal feed. Cottonseed oil soapstock (foots) is the principal by-product of cottonseed oil refining. Cottonseed soapstocks are being increasingly used as animal feed additives; cottonseed hulls are used as a source of additional fiber in animal feeds and contain much lower gossypol concentrations than do whole cottonseeds.

Lipid-soluble gossypol is readily absorbed from the GI tract. It is highly protein-bound to amino acids, especially lysine, and to dietary iron. The precise mechanism of action is not known, but gossypol renders many amino acids unavailable by the formation of a Schiff's base-type derivative as well as additional protein/gossypol interactions. Gossypol also affects enzymatic reactions critical for many biologic processes, including the ability of cells to respond to oxidative stress and inhibition of oxygen release from hemoglobin. Conjugation, metabolism, and urinary excretion of gossypol is limited; most is eliminated in the feces.

All animals are susceptible, but monogastrics, preruminants, immature ruminants, and poultry appear to be affected most

Gossypium spp (cotton plant), young plant. Courtesy of Dr. Cecil Brownie.

frequently. Adult ruminants are able to detoxify gossypol by formation of stable complexes with soluble proteins in the rumen, thus preventing absorption, something lacking in swine, preruminants, and young ruminants with only a partially functioning rumen. Pigs, guinea pigs, and rabbits are reported to be sensitive. Dogs and cats appear to have intermediate sensitivity. Goats may be more sensitive to gossypol than are cattle. Horses appear relatively resistant but caution is still advised. Toxic effects usually occur only after long-term exposure to gossypol, often weeks to months.

Clinical Findings: Signs may relate to effects on the cardiac, hepatic, renal, reproductive, or other systems. Prolonged exposure can cause acute heart failure resulting from cardiac necrosis. Also, a form of cardiac conduction failure similar to hyperkalemic heart failure can result in sudden death. Pulmonary effects, labored breathing, and chronic dyspnea are most likely secondary to cardiotoxicity from congestive heart failure.

Hepatotoxicity can be a primary effect from direct damage to hepatocytes or metabolism of phenolic compounds to reactive intermediates, or liver necrosis may be secondary to congestive heart failure. Gossypol inhibits glutathione-S-transferase, impairing the liver's ability to metabolize xenobiotic compounds. Hematologic effects include anemia with reduced numbers of RBCs and increased RBC fragility, decreased oxygen release from oxyhemoglobin, and reduced oxygen-carrying capacity of blood with lowered Hgb and PCV values due to complexing of iron by gossypol.

Reproductive effects include reduced libido with decreased spermatogenesis and sperm motility, as well as sperm abnormalities (which are reversible) resulting from enzyme inhibition of steroid synthesis in testicular Leydig cells. Specific mitochondrial damage in spermatozoa appears to cause immobility and depressed sperm counts. Extensive damage to germinal epithelium in both rams and bulls fed excessive gossypol may be responsible for depressed spermatogenesis. Effects in females may include irregular cycling, luteolytic disruption of pregnancy, and direct embryotoxicity; probable mechanisms include an endocrine effect on the ovary as well as a direct cytotoxic effect on the uterus or embryo. Green discoloration of egg yolks and decreased egg hatchability have been reported in poultry. However, antifertility and reproductive effects in many

nonruminant species are secondary to the more toxic effects, particularly in females.

Signs of prolonged excess gossypol exposure in many animals are reduced growth rate, weight loss, weakness, anorexia, and increased susceptibility to stress. Young lambs, goats, and calves may suffer cardiomyopathy and sudden death; if the course is more chronic, they may be depressed, anorectic, and have pronounced dyspnea. Adult dairy cattle may show weakness, depression, anorexia, edema of the brisket, and dyspnea, and also have gastroenteritis, hemoglobinuria, and reproductive problems. In monogastric animals, acute exposure may result in sudden circulatory failure, whereas subacute exposure may result in pulmonary edema secondary to congestive heart failure; anemia may be another common sequela. Violent dyspnea ("thumping") is the outstanding clinical sign in pigs. In dogs, gossypol poisoning is primarily reflected by cardiotoxic effects; condition deteriorates progressively, and ascites may be marked. Affected dogs may show polydipsia and have serum electrolyte imbalances, most notably hyperkalemia, with pronounced ECG abnormalities.

Lesions: An enlarged, flabby, pale, streaked, and mottled heart with pale myocardial streaking, enlarged and dilated ventricles, and valvular edema may be evident. Skeletal muscles may also be pale. A froth-filled trachea and edematous, congested lungs are common, with interstitial pulmonary edema and markedly edematous interlobular septa. Generalized icterus and an enlarged, congested, mottled or golden, friable "nutmeg" liver with distinct lobular patterns may be seen. The kidneys, spleen, and other splanchnic organs may be congested, possibly with petechiae; mild renal tubular nephrosis may be present. Hemoglobinuria and edema and hyperemia of the visceral mucosa may develop. Cardiomyopathy in affected dogs has been characterized as focal or general, granular myocardial degeneration with edema between and within myofibers; severe abnormalities in contractility have resulted in right-side congestive heart failure without pronounced dilatation, and pulmonary or hepatic changes can be minimal.

Diagnosis: Diagnosis is based on the following: 1) a history of dietary exposure to cottonseed meal or cottonseed products over a relatively long period; 2) signs, especially sudden death or chronic dyspnea, affecting multiple animals within a group; 3) lesions consistent with the reported

syndrome and associated cardiomyopathy and hepatopathy, with increased amounts of fluids in various body cavities; 4) no response to antibiotic therapy; and 5) the presence of significant concentrations of free gossypol in the diet. Analyses of dietary components for free gossypol must be correlated with history, clinical signs, and postmortem findings. However, as with many feed-induced toxicoses, the responsible feed may be already completely consumed and not available for analysis. Free gossypol at >100 mg/kg (100 ppm) of feed in the diet of pigs or young ruminants <4 mo old supports a presumptive diagnosis. Adult ruminants can detoxify higher concentrations of gossypol, but intake should still be <1,000 ppm in the diet. Gossypol toxicosis developed in mature dairy goats each fed an estimated 350–400 mg gossypol/day for 3 mo in a diet containing ~400 ppm free gossypol. Adverse effects on semen quality (decreased sperm motility and morphologic abnormalities) occurred in young bulls fed a concentrate containing 1,500 ppm free gossypol (providing 8.2 g free gossypol/head/day). Cottonseed meal containing 26.6% (266,000 ppm) total gossypol and 0.175% (1,750 ppm) free gossypol was toxic when fed to adult dogs for an unspecified length of time; however, the equivalent oral dosage of free gossypol fed was <6 mg/kg/day.

Gossypol can gradually accumulate in the kidneys and liver, which are additional specimens for postmortem analyses. In sheep, gossypol concentrations (free or bound) >10 ppm in the kidneys and >20 ppm in the liver suggest excess gossypol exposure. However, background and significantly increased tissue gossypol concentrations have not been determined in all animal species, so tissue analyses may be of limited diagnostic value.

Differential diagnoses include poisonings by cardiotoxic ionophoric antibiotics (eg, monensin, lasalocid, salinomycin, narasin) and anmonia, nutritional or metabolic disorders (eg, selenium, vitamin E, or copper deficiency), infectious diseases, noninfectious diseases (eg, pulmonary adenomatosis, emphysema), mycotoxicoses caused by *Fusarium*-contaminated grain, and toxicoses caused by plants with cardiotoxic and other effects. Cardiotoxic plants (see p 3103), which may cause confusing or similar clinical signs and postmortem lesions, include English yew (*Taxus baccata*), Japanese yew (*T. cuspidata*), laurel (*Kalmia* spp), azalea (*Rhododendron*

spp), oleander (*Nerium oleander*), yellow oleander or yellow-be-still tree (*Thevetia peruviana*), purple foxglove (*Digitalis purpurea*), lily-of-the-valley (*Convallaria majalis*), dogbane (*Apocynum* spp), coffee senna (*Senna occidentalis*), bracken fern (*Pteridium aquilinum*), white snakeroot (*Eupatorium rugosum*), death camas (*Zygadenus* spp), lantana (*Lantana camara*), monkshood (*Aconitum napellum*), and milkweed (*Asclepias* spp).

Prevention, Treatment, and Control:

There is no effective treatment for gossypol poisoning. Adsorbents such as activated charcoal and saline cathartics are of little value because of the chronic exposure and cumulative nature of gossypol. If gossypol toxicity is suspected, all cottonseed products should be removed from the diet immediately. However, severely affected animals may still die up to 4 wk after withdrawal of gossypol from the diet. Recovery depends primarily on the extent of toxic cardiopathy. Because exposure is usually chronic, and life-threatening lesions may be advanced before a diagnosis is made, a favorable prognosis for complete recovery may be unrealistic. Mild to moderate myocardial lesions may be reversible with time if stress is minimized and animals are carefully handled. However, poor weight gains in affected livestock and increased susceptibility to stress may persist for several weeks after cottonseed products are removed from the diet. A high-quality diet supplemented with lysine, methionine, and fat-soluble vitamins should be included in supportive therapy. Selenium or copper deficiencies may potentiate gossypol toxicosis.

A high intake of protein, calcium hydroxide, or iron salts appears to be protective in cattle. Mature cattle should also be given ≥40% of dry-matter intake from a forage source, and dietary gossypol concentrations should be limited to ≤1,000 ppm, because 1,500 ppm may cause anemia, poor growth, or decreased milk production. Swine and young ruminants are affected by dietary gossypol concentrations >100 ppm. Added iron of up to 400 ppm in swine diets and up to 600 ppm in poultry diets was reported to be effective in preventing signs and tissue residues of dietary gossypol exposure when used in ratios of 1:1 to 4:1 of iron to free gossypol. Poultry are affected by dietary gossypol concentrations >200 ppm.

POISONOUS MUSHROOMS

Mushrooms are the fruiting bodies of a variety of fleshy fungi that are found worldwide. They typically appear suddenly from growing vegetative (mycelium) portions, and they contain spores as reproductive units. Fungi lack chlorophyll; their nutritional requirements are met by utilizing organic material from a saprophytic, parasitic, and/or mycorrhizal life cycle.

Exposure is by ingestion. Although most mushrooms are edible and safe, a few contain diverse secondary metabolites (cyclopeptides, monomethylhydrazine, orelline/orellanin, muscarine, ibotenic acid and muscimol, psilocybin, and unknowns) that on ingestion/absorption result in mild to severe illness and even death. The mushroom species most frequently implicated in human/animal mushroom fatalities globally is *Amanita phalloides*. Most *Amanita* species are typically identified by their physical characteristics: veil (universal/partial), cap or pileus (with scales—remnants of universal veil), lamellae (gill-like, spore-bearing structure under surface of pileus), spores (reproductive structure—white to black and other shades of color), stipe/stalk (cap support), annulus or ring (remnant of partial veil on stipe below pileus), volva (remnant of universal veil at base of bulb), and mycelium. Other characteristics helpful in the identification of some poisonous mushrooms are listed in TABLE 5.

The time lapse (latent period) between mushroom ingestion and observed clinical

Amanita phalloides. Courtesy of Dr. Cecil Brownie.

signs in exposed animals largely dictates the prognosis. A long delay time is synonymous with fatality (TABLE 6). However, short latent periods do not always indicate survival, because the animal may have ingested a

TABLE 5

PHYSICAL CHARACTERISTICS OF COMMON POISONOUS MUSHROOMS

Genus and Species	Color of Cap/Spores	Habitat	Season	Range
<i>Amanita muscaria</i>	Red-tan to yellow/orange/ white	Ground-pine, spruce, birch, poplar, and oak trees	Autumn/winter: June–Nov	Widespread, common in East and California
<i>A pantherina</i>	White with whitish patches; dark to yellow-brown/white at margin	Ground under conifers (Douglas fir)	Autumn/winter: June, Sept–Oct, Nov–Feb (California)	Rocky Mountains/ West coast; rare in East

(continued)

TABLE 5 PHYSICAL CHARACTERISTICS OF COMMON POISONOUS MUSHROOMS (*continued*)

Genus and Species	Color of Cap/Spores	Habitat	Season	Range
<i>A phalloides</i>	Yellow/green or green/white	Ground under conifers, hardwoods; junipers and oaks	Autumn: late Sept–Nov, Nov–Jan	Massachusetts to Virginia west to Ohio; Pacific northwest to California
<i>A virosa</i>	White/white	Ground; mixed woods; grass, near trees	Autumn: late June–early Nov	North America
<i>Chlorophyllum molybdites</i>	White/green or grayish white	Lawn, pastures, meadows, fairy rings	Summer: Aug–Sept	Florida to California, common in Denver, reported in New York and New Jersey
<i>Clitocybe</i> spp	White/white	Ground	Perennial	Widespread in North America
<i>Cortinarius orellanus</i>	Orange/brown	Ground under conifers	July–Aug; Sept–Oct (Rocky Mountains)	Widespread in North America
<i>Galerina</i> spp	Brown-orange/rust-brown	Ground-wood, well-decayed conifers and logs	Autumn/spring: Oct–Nov, May–June	Throughout North America
<i>Gyromitra esculenta</i>	Brown-rust/yellow to buff	Ground under conifers	Spring: April–early June	Throughout North America
<i>Inocybe</i> spp	Brown/bright rust/orange-brown or dull gray-brown	Ground	Autumn: May–Nov	Widespread in North America
<i>Lepiota</i> spp	White with brownish scales/white	Ground under conifers, grass, leaf litter, oak and mixed woods	July–Oct (Michigan, Ohio); July–Nov (Florida); Nov–Feb (California)	Throughout North America
<i>Paxillus involutus</i>	Brown/sienna (clay-brown)	Ground: single/numerous on wood in mixed woods	July–Nov	Widespread in North America
<i>Psilocybe cubensis</i>	Brown/lilac brown to dark purple brown	Ground/wood/dung (cattle, horses)	Year round	Gulf Coast
<i>Russula emetica</i>	Reddish/white to yellowish white/whitish	Single/group; on sphagnum moss, rarely on very rotten wood, conifers, or mixed woods	July–Sept	Widespread in North America

TABLE 6

POISONOUS MUSHROOMS: ONSET OF ACTION AND ORGANS TARGETED

Mushrooms	Toxin	Onset Time	Organ/System
LATENT PERIOD >6 HR AFTER INGESTION; LIFE-THREATENING			
<i>Amanita phalloides</i> ; <i>A virosa</i>	Cyclopeptides, α and β amanitins, phallotoxins, virotoxins	6–24 hr, rarely >24 hr	Primarily liver, kidney secondary
<i>Conocybe filaris</i>	α and β amanitins	6–14 hr, rarely >24 hr	Primarily liver
<i>Cortinarius gentilis</i>	Orellanin, orelline	3–14 days (days/weeks)	Primarily renal ^a
<i>Galerina autumnalis</i> ; <i>G venenata</i>	α and β amanitins	6–14 hr, rarely >24 hr	Primarily liver
<i>Gyromitra esculenta</i>	Monomethylhydrazine	6–24 hr	CNS
<i>Lepiota</i> spp	α and β amanitins	6–14 hr, rarely >24 hr	Primarily liver
LATENT PERIOD $\leq$3 HR AFTER INGESTION; NOT LIFE-THREATENING			
<i>Amanita muscaria</i> ; <i>A pantherina</i>	Isoxazoles: ibotenic acid muscimol	30 min–2 hr; recovery 4–24 hr	CNS
<i>Chlorophyllum molybdites</i>	Unknown	30 min–3 hr; recovery 1–2 days	GI
<i>Clitocybe dealbata</i> ; <i>Clitocybe</i> spp; <i>Inocybe</i> spp	Muscarine	30 min–2 hr; recovery 6–24 hr	Autonomic nervous system
<i>Paxillus involutus</i>	Unknown	1–3 hr; recovery 2–4 days	Immune system
<i>Psilocybe</i> spp; <i>Conocybe smithii</i> ; <i>Gymnopilus spectabilis</i> ; <i>Panaeolus subbalteatus</i>	Psilocybin and psilocin	30–60 min; rarely 6 hr	CNS
<i>Russula emetica</i>	Unknown	30 min–3 hr; recovery 1–2 days	GI

^a No reported veterinary cases

combination of non-lethal/lethal mushroom species growing in the same location (dilution effect, or dose determines toxicity). In mushroom species with clinical signs that appear <3 hr after ingestion, effects are generally self-limiting and not life-threatening. Those with clinical signs that appear >6 hr after ingestion are life-threatening.

The sudden appearance of mushrooms and their short lifespan within the environment, coupled with the indiscriminate eating habits of many animals, creates diagnostic challenges. History and time after ingestion at which clinical signs are seen determine the treatment approach and prognosis. Establishing the time of ingestion may be difficult to impossible. With no proven antidotes to treat mushroom poisonings, treatment is primarily directed at decontamination, mushroom identification when possible, and intensive supportive care.

TOXIN LATENT PERIOD <3 HR AFTER INGESTION

Clitocybe dealbata, *C dilatata*, and *Inocybe* spp

Clitocybe are fleshy, small mushrooms with white-tan-grey caps, gills that are attached and that descend the stalk, and white spore print. They are widely distributed and usually grow on the ground in open woods, parks, and lawns. *Inocybe* are small, brown mushrooms that grow on conifers or broad-leaved trees and oak woods (mycorrhizal). They have a cap with a knob, ringless stalk, veil covered immature gills, no remnant of universal veil, and a spore print that is bright rust/orange-brown or gray-brown.

The toxin in these mushrooms is muscarine, a quaternary ammonium compound that is poorly absorbed orally and does not cross the blood-brain barrier. Its cholinergic effects are therefore peripheral. The absorbed portion is quickly distributed throughout the body and undergoes urinary excretion. Muscarine is structurally similar to acetylcholine, a cholinergic neurotransmitter. Whereas the acetylcholine-muscarine receptor complex is susceptible to acetylcholinesterase inactivation, the muscarine-muscarine receptor complex is not. Muscarine competes with acetylcholine at cholinergic receptor binding sites, leading to excessive stimulation of postganglionic cholinergic fibers and the subsequent observed clinical signs (cholinergic excess).

Clinical Findings: Within 30–120 min of ingestion, there is mild to excessive cholinergic stimulation—ataxia, vomiting, abdominal pain, salivation, lacrimation, watery diarrhea, miosis, bronchoconstriction, bradycardia, arrhythmias, hypotension/hypertension, and shock.

Diagnosis: Diagnosis may be based on a history of mushroom ingestion, identification of suspected mushroom and consistent clinical signs, response to supportive care, and atropine therapy. Tests used to evaluate fluid and electrolyte status in severe gastroenteritis cases, together with a liver profile, may be useful.

Treatment: Other than offering supportive care (fluid and electrolyte replacement), treatment is unnecessary in most cases. In life-threatening cases, atropine therapy (0.2–2 mg/kg, a portion of the calculated dose given IV and the remaining portion IM or SC), repeated as necessary, is the treatment of choice. Efficacy of treatment should be based on lack of respiratory difficulties and respiratory secretions and not on mydriasis. Excessive atropine therapy can lead to anticholinergic effects (eg, tachycardia, GI stasis, behavioral changes, and hyperthermia); therefore, animals should be monitored.

Amanita muscaria and *A pantherina*

Amanita muscaria have an orange-red cap with distinctive white to yellow warts, gills that are somewhat attached, white spore print, ring stalk, and bulbous base (cup). *A pantherina* have a tan to yellow-brown/dark brown cap with white patches, a ringed stalk with basal bulb, and white spore print. Both of these mushrooms are found in coniferous and deciduous forests of the Pacific northwest.

The toxins in these mushrooms are isoxazole derivatives: ibotenic acid, which is structurally similar to the stimulatory neurotransmitter glutamic acid, and its decarboxylated metabolite muscimol, which is stereochemically similar to the inhibitory neurotransmitter γ -aminobutyric acid (GABA). They both cross the blood-brain barrier and effect functional changes within the CNS. The toxic dose of ibotenic acid is reported to be 30–60 mg, and that of muscimol is 6 mg (ingestion of more than two mushrooms).

Ibotenic acid undergoes spontaneous decarboxylation (stomach, liver, and brain), forming muscimol, which is a GABA-receptor agonist. Both are analogues of

γ-aminobutyric acid and act as weak, noncompetitive inhibitors of GABA (inhibits neuronal and glial GABA uptake). This reduces the inhibitory effect of the Purkinje cells in the cerebellum, increases brain serotonin, and decreases catecholamine levels.

Clinical Findings: Both compounds are rapidly absorbed from the GI tract. The onset of clinical signs (tachycardia, hypotension, ataxia, seizures, hyperthermia, vomiting, muscle fasciculation, mydriasis, incoordination, hyperactivity [paddling, chewing movements], opisthotonos, respiratory depression, coma, and death) are reportedly seen within 30–120 min after ingestion. Duration of signs is ~24 hr.

Diagnosis: Diagnosis is based on a history of ingestion, clinical presentation, and response to treatment (symptomatic, supportive, and specific drugs, eg, benzodiazepine).

Treatment: Symptomatic and supportive treatment includes maintaining hydration (IV fluids), keeping airways free of respiratory secretions, and frequent positional changes. Seizures may be controlled with diazepam (0.5 mg/kg, IV to effect; repeated as needed), phenobarbital (6 mg/kg, IV), or pentobarbital (5–15 mg/kg, IV). Benzodiazepines and barbiturates are GABA-receptor agonists and may potentiate CNS and respiratory depression. Muscarine concentrations in *A muscaria* are very low, and peripheral effects are more anticholinergic than cholinergic. Therefore, atropine therapy is contraindicated.

Chlorophyllum molybdites* and *Russula emetica

Chlorophyllum molybdites mushrooms have caps that are large, white to brown, egg-shaped, convex knobbed to flat, with numerous cinnamon or buff scales. They have unattached white gills, green or grayish-olive spores, and a ring on the stalk. They are common in the southern and central USA. *Russula emetica* mushrooms have a reddish, slimy cap with short whitish stalk and gills; no veils; and a white to yellowish-white spore print. They grow singly or in a group and are found throughout the USA. The toxins in these mushrooms are varied and unknown GI irritants that are thought to be high-molecular-

weight proteins found throughout the mushroom.

Clinical Findings: Within minutes to hours (0.5–3 hr) after exposure, clinical signs become evident. These include vomiting, bloody diarrhea, abdominal pain, muscle cramps, liver injury, and circulatory disturbances that are self-limiting. Although recovery generally occurs within 6–24 hr, it could be prolonged or become life threatening (rare) in cases of hypovolemic shock, oliguria, and/or transient increased BUN secondary to dehydration. Death is rare.

Diagnosis: A tentative diagnosis may be based on history and early onset of reported clinical signs (gastroenteritis—vomiting and bloody diarrhea). Except for dehydration, there are no systemic signs. If the mushroom is available, the gills (light green) and spore print (green) color may be used to distinguish *C molybdites*, the most common GI irritant mushroom species, from others.

Treatment: There are no specific antidotes. Dehydration and electrolyte imbalance should be addressed. Gastric lavage and activated charcoal therapy may be considered. Analgesics are useful in some cases, but caution should be exercised in administering acetaminophen (inherently hepatotoxic) to hepatic insult cases. Phenothiazines interact adversely with toxins to induce CNS and/or GI effects. Fluids and vasopressors should be administered in hypovolemic shock cases. Liver and kidney functions should be monitored.

Psilocybe cubensis*, *Conocybe cyanopus*, *Gymnopilus spectabilis*, and *Panaeolus subbalteatus

Psilocybe cubensis are small, brown, slender-stalked mushrooms. They commonly grow in piles of dung and fertilized grasses in moist areas throughout the USA, especially in the southeastern and northwest regions. The mushrooms develop a blue-green color in handled and injured areas. They have yellowish, sticky to moist caps with brown gills; a persistent ring on the stalk; and a purple-brown spore print. *Conocybe cyanopus* are small and fragile, with brown caps, brown gills, and a large ring midway down the long, thin stalk. The spore print is cinnamon brown. They are

widely distributed in North America. *Gymnopilus spectabilis* are large yellow-orange mushrooms with an orange to rust orange spore print. They are found in clusters on wood, stumps, or on the ground over buried wood. *Panaeolus subbalteatus* have broadly conical to flat caps with a dark belt around margin, brown gills, hairy reddish stalks, and a blackish spore print. They are widely distributed in North America.

These hallucinogenic mushrooms contain psilocybin and psilocin, which are indole alkaloids similar to lysergic acid diethylamide (LSD). Psilocybin undergoes rapid dephosphorylation (plasma, kidneys, and liver), forming psilocin, which is structurally similar to serotonin (stimulatory to serotonin receptors in the central and peripheral nervous systems). Metabolites cross the blood-brain barrier and concentrate in brain tissue. Growth conditions, geographic location, storage conditions, and mushroom species are factors that influence toxin concentrations. Ingestion of five or six dried mushroom caps is reported to be toxic.

Clinical Findings: Clinical signs occur within 0.5–1 hr; they are rarely delayed as long as 3 hr after ingestion. Signs include vocalization, aggression, nystagmus, ataxia, tachycardia, vomiting, urinary incontinence, dyspnea, mydriasis, weakness, hyperthermia, mild methemoglobinemia, and hallucination, with recovery within 6 hr of observed clinical signs.

Diagnosis: A history of mushroom ingestion, identification of suspected mushroom(s), consistent clinical presentation, and response to supportive and symptomatic care are critical for diagnosis. With isoxazole-induced toxicity, coma is distinctly expressed; however, the opposite is true in psilocin-induced toxicity. Tests detecting psilocin and its glucuronide metabolite in urine, serum, and blood, although confirmatory, are not widely available clinically.

Treatment: Treatment is primarily symptomatic and supportive. Diazepam (0.5–1 mg/kg, IV, with incremental dose increase of 5–10 mg to effect) or phenobarbital (6 mg/kg to effect) may be given. Body temperature should be monitored. In some cases, leaving the animal untreated in a quiet, dark environment might be all that is necessary.

TOXIN LATENT PERIOD >6 HR AFTER INGESTION

Amanita phalloides, *A virosa*, *Lepiota helveola*, *Galerina autumnalis*, *G venenata*, and *Conocybe filaris*

These mushroom species account for >95% of the reported mushroom-induced deaths. They are common throughout North America and are associated with oaks and birch trees.

Amanita phalloides and *A virosa* have olive to green caps with veil patches, gills that are unattached to the stalk, a white spore print, and stalks with a ring (often but not always) and a cup (volva) or remnants at the base. The features of *Lepiota helveola* are similar to those of *Amanita* spp but without volva; they have scaly caps with a knob in the center and stalks with a movable ring. *Galerina autumnalis* (autumn galerina), *G venenata*, and *Conocybe filaris* have brownish, tacky caps with yellowish gills becoming rust and a ring on their brownish stalks. They have no volva, and their spore print is brown to rust-brown. These species are abundant on well-decayed coniferous and deciduous logs throughout North America.

Toxin present in these mushrooms include cyclopeptide amatoxins (bicyclic octapeptides), phallotoxins, and virotoxins (bicyclic heptapeptides). Amatoxins (α and β amanitin derivatives) are the most potent; they are not found in all *Amanita* spp. An estimated reported lethal dose is 0.1 mg/kg (equivalent to the concentrations in one cap of *A phalloides*) across animal species. Whereas the amatoxins are reported to be well absorbed orally, phallotoxins and virotoxins are not. Amanitins are not protein bound and are excreted in urine (80%–90%), feces, and bile (7%). Amatoxins bind to nuclear RNA polymerase-11 (transcription phase), thus preventing the formation of phosphodiesterase bonds and subsequent RNA, DNA, and protein synthesis. High-protein synthesis cells are most sensitive. Amatoxins are primarily liver toxins, but they also affect many organ systems, resulting in hypoglycemia, blood clotting defects, thyroid/parathyroid functional anomalies, renal failure, and intestinal damage (enterohepatic recirculation of the toxin).

Clinical Findings: Signs can be characterized in four phases: 1) latent (6–12 hr after

ingestion), in which the animal shows no clinical signs; 2) GI signs (as long as 24 hr after ingestion); 3) remission (as long as 72 hr after ingestion), in which the animal appears to have recovered; and 4) hepatic/renal (3–6 days after ingestion), leading to recovery or death throughout the next 7–14 days. The reported long latent phase is of diagnostic importance. The GI phase, indicated by vomiting, abdominal discomfort, hepatitis, and pancreatitis follows and signals initial hepatic, hematologic, cardiovascular, endocrine, CNS, and renal changes. The remission phase follows, only to enter a fulminant hepatic/renal phase, indicated by icterus, hypoglycemia, and coma, 3–4 days after ingestion. Recovery or death (>50%) from hepatic and/or renal failure occurs 7–14 days after mushroom ingestion.

Diagnosis: Mushroom identification characteristics, coupled with consistent clinical signs as stated above, is diagnostic. Meixner test results (time taken, and color intensity of suspected mushroom specimen—fresh, vomited fragments) would be diagnostic. During the GI phase, animals should be monitored for decreased serum thyroxine levels, hypoglycemia, and/or increased insulin, calcitonin, and parathyroid levels. Routine blood and serum chemistry profiles are unremarkable until liver/kidney damage. Because the toxin is primarily hepatotoxic, changes in clotting factor V, fibrinogen, and kidney and liver profiles would also be helpful. Amanitins can be detected in urine from animals not showing clinical signs. They are also detectable in liver and kidney specimens as long as 22 days after ingestion.

Treatment: There are no specific antidotes. Silibinin (not FDA approved), penicillin G (high levels), combined silibinin/penicillin, cimetidine, *N*-acetylcysteine, or vitamin C therapies have been used with some success in people and could therefore be tried, although animal study data are not readily available. Hypoglycemia remains an adverse effect with or without treatment. Supportive care (IV fluids, dextrose, and antibiotics) counters the effects of severe liver and kidney damage. Early institution of treatment is essential to save the animal; the prognosis is poor after hepatic/renal pathology. Activated charcoal (1 g/kg with cathartic) during the first 24 hr after ingestion absorbs amanitin undergoing enterohepatic recirculation and thus may be helpful.

Gyromitra esculenta

These mushrooms have a non-gilled, yellow-brown to dark-red, deeply wrinkled, honeycomb (unlike true morels that are hollowed and not chambered), saddle-shaped cap on a short stalk. They are found on the ground under conifers throughout North America. The toxin involved is the hydrazone gyromitrin, which on ingestion is hydrolyzed to *N*-methyl-*N*-formylhydrazine (depletes hepatic cytochrome P-450) and monomethylhydrazine (inhibitor of the coenzyme pyridoxal phosphate and γ -aminobutyric acid in the CNS 6–12 hr after ingestion. The concentration of gyromitrin varies with environmental conditions.

Clinical Findings: Vomiting, watery diarrhea, abdominal discomfort, convulsions, and coma may be noted 6–24 hr after ingestion of a toxic dose. Methemoglobinemia and hemolytic anemia, hepatitis, jaundice, nephritis, and death develop some time later. Death appears to be due to hepatorenal failure.

Treatment: Activated charcoal (1 g/kg) may be helpful if given early after ingestion. IV fluids should be given as needed. IV pyridoxine controls neurologic signs, and methylene blue can be given in cyanotic and methemoglobin cases. Pyridoxine-induced peripheral neuropathy from administering high doses should be avoided. For the induced hepatic encephalopathy, supportive therapy is essential. In addition to monitoring methemoglobin levels, hepatic and renal functions should also be monitored.

TOXIN LATENT PERIOD >24 HR AFTER INGESTION

Cortinarius orellanus* and *C rainierensis

These mushrooms have a colorful but mostly brownish cap, stalk, and young gills; the matured gills are orange-rust in color. The spore print is bright rust/orange-brown/gray-brown but not purple-brown. Stalks may or may not have a ring-like zone.

The toxins involved are orelline and orellanine, which are chemically related to the herbicide diquat (bipyridyl derivatives). Thin-layer chromatography can detect orellanine in renal biopsy material long after clinical exposure but not in urine and/or blood during clinically active states. Ingestion of three to ten caps is reported to be lethal. There have been no reported cases from ingestion of species grown in North America.

Clinical Findings: The onset of clinical signs is delayed (17 days after ingestion). Signs include anorexia, vomiting, diarrhea/constipation, gastritis, thirst, and polyuria progressing to oliguric renal failure in 3–14 days after initial clinical signs. The kidney seems to be the target organ; lesions include interstitial nephritis, tubular damage, and fibrosis. Hepatic damage is infrequently reported. In most cases, marked improvement over an extended period (6 mo) is seen; however, chronic renal failure occurs in some cases.

Diagnosis: Urinalysis indicates concentrated urine, hematuria, protein, and RBC casts early in the latent period, followed by diluted urine with protein and few casts later. It therefore becomes necessary to monitor renal function. Renal pathology without hepatic involvement after a long latent period (days) has been reported in people. Blood, urinalysis, and kidney profile testing would be supportive. Mushroom identification can differentiate *Cortinarius* spp from *Paxillus involutus*, a mushroom reported to cause hypersensitivity leading to renal failure.

Treatment: Treatment should be focused on decontamination, mushroom identification (often difficult), and intensive supportive care. Hemodialysis should be instituted until normal kidney function returns. Pentobarbital and/or furosemide usage should be avoided or limited, because these drugs increase toxicity.

MISCELLANEOUS POISONOUS MUSHROOMS

Ramaria flavo-brunnescens

Ramaria flavo-brunnescens is found exclusively in eucalyptus woods in North America, Australia, Brazil, and Uruguay, and is easily identified from the spore print color of pale buff to brownish yellow. It is reported to be poisonous to ruminants (cattle and sheep). The toxin is an unknown, volatile compound or compounds found throughout the plant that is reported to

interfere with sulfur-containing amino acid incorporation. Drying decreases toxicity.

Clinical Findings: Signs may appear as early as 3 days but as long as 6 days after exposure and include anorexia, diarrhea, salivation, hyperthermia, depression, hyperemic coronary band, hemorrhage (anterior chamber of eyes), oral ulceration, altered keratinization (hair/hoof loss, similar to selenium poisoning), and recumbency. Death or recovery may be expected in 3–15 days.

Diagnosis: These mushrooms grow exclusively among eucalyptus plants, so history of exposure to eucalyptus is key. Selenium exposure and toxicity causes similar signs. The duration and outcome of the clinical expression helps to confirm diagnosis.

Treatment: Treatment involves removing the affected animal from the source and offering supportive care. Recovery requires time.

Paxillus involutus

Paxillus involutus has a dry or slimy, brownish cap with an in-rolled margin and yellowish gills descending a short distance on the brown, smooth stalk. The spore print is clay-brown. *P. involutus* is widely distributed in North America. It may appear singly or in groups of several, near or on wood in mixed woods in the spring/autumn. The toxin is unknown, but it may cause hypersensitivity over time, leading to kidney failure.

Clinical Findings: Vomiting, diarrhea, cardiovascular irregularity, and RBC destruction may be noted 1–3 hr after ingestion. Recovery generally takes 2–4 days but could be longer. Acquired sensitivity develops over time.

Diagnosis and Treatment: A diagnosis can be made based on mushroom identification, consistent clinical signs, and response to supportive care. Treatment involves symptomatic and supportive measures.

POISONOUS PLANTS

HOUSEPLANTS AND ORNAMENTALS

Plants are an important part of the decor of homes; pets having access to these plants often chew on or ingest them, with toxicity a possible outcome (*see* TABLE 7). Inquiries to poison control centers on plants ingested by children <5 yr old are estimated at 5%–10% of all inquiries. Similar estimates (although not documented) could be made for pets.

Little research has been done on the toxicity of houseplants. Most are hybrids, and selecting for growth outside their natural environment could affect their degree of toxicity. Age of the pet, boredom, and changes in the surroundings are factors that may affect the incidence of poisoning. Puppies and kittens are very inquisitive, and mouth or chew almost any and everything. Pets (especially single household pets) of all ages may become bored or restless if left alone or confined for too long at any one time, and chewing on objects for relief is common. Pets of all ages also explore changes in their environment (eg, pets commonly chew the leaves or ripe berries of potentially poisonous plants placed in the home during holidays).

RANGE PLANTS OF TEMPERATE NORTH AMERICA

Poisonous plants are among the important causes of economic loss to the livestock industry and should be considered when evaluating illness and decreased productivity (*see* TABLE 8). Poisonous plants can affect animals in many ways, including death, chronic illness and debilitation, decreased weight gain, abortion, birth defects, increased parturition interval, and photosensitization. In addition to these more obvious losses, other considerations include loss of forage, additional fencing, increased labor and management costs, and frequently interference with proper harvesting of forage.

Most poisonous range plants fall into two general categories: those that are indigenous to a range and increase with heavy grazing, and those that invade after overgrazing or disturbance of the land. Among those not in these categories are certain locoweeds and larkspurs, both of

which form part of the normal range plant community. Poisonous plants can be found in most plant communities and should be considered in most grazing situations.

Livestock poisoning by plants often can be traced to problems of management or range condition, rather than simply to the presence of poisonous plants. Usually, animals are poisoned because hunger or other conditions cause them to graze abnormally. Overgrazing, trucking, trailing, corralling, or introducing animals onto a new range tend to induce hunger or change behavior, and poisoning may occur.

Not all poisonous plants are unpalatable, and they are not restricted to overgrazed ranges and pastures. Furthermore, poisonous plants do not always kill or otherwise harm animals when consumed; the dose determines toxicity. Many plants can be either useful forage or toxic. For example, plants such as lupine and greasewood may be part of an animal's diet, and the animal is poisoned only when it consumes too much of the plant too fast. To prevent poisoning, it is important to understand the factors involved when a useful forage becomes a poisonous plant.

Definitive diagnosis of suspect plant poisonings is difficult. It is important to be familiar with the poisonous plants growing in the specific area and the conditions under which livestock may be poisoned. A tentative diagnosis is possible if the following information is available: 1) any local soil deficiencies or excesses (which may complicate plant toxicities or simply confuse as to cause of a syndrome), 2) the syndromes associated with each of the poisonous plants in the area, 3) the time of year during which each is most likely to cause problems, 4) the detailed history of the animal(s) over the last 6–8 mo, and 5) any change of management or environmental condition that may cause an animal to change its diet or grazing habits (in some cases, eg, locoism, this may be all that is required in addition to identification of the plant involved). Identification of the plant is important, whatever its stage of growth, and is especially useful if it can be identified in the stomach contents of the poisoned animal. Chemical analysis of toxicants often is not useful. Metabolic profiles are useful for some toxicities, and in some, the necropsy lesions are distinctive (*see* TABLE 8).

TABLE 7 POISONOUS HOUSEPLANTS AND ORNAMENTALS*

Scientific Name (Family)	Common Name	Important Characteristics
<i>Abrus precatorius</i> (Fabaceae)	Rosary pea, Precatory bean, Prayer beads, Crab's eye	Climbing/twining vine on other objects as substratum. Compound leaves/light sensitive, pale reddish purple flowers, pea-shaped pods with 3–5 red seeds with black spots. Jewelry handicrafts as souvenir gifts in homes.
<i>Adenium obesum</i> (Apocynaceae)	Desert rose, Mock azalea, Desert azalea	Succulent shrubs or small trees. Perennials, milky viscous sap with fleshy swollen stems. Simple, fleshy to leathery, lanceolate, dark leaves. Showy flower clusters—red petals with pink or white centers at tip of branch. Fruits—follicles with many seeds. Houseplant grown outside in dry, hot locations.
<i>Agapanthus orientalis</i> (Liliaceae)	African blue lily, Blue African lily	Grows to a height of ~2 ft in large containers. Perennial herbs with simple, heart-shaped, thin, highlighted veins, variegated leaves; yellow-green spathe; grown from rhizomes.
<i>Agave americana</i> (Agavaceae)	Century plant, American aloe	Clumps of thick, long strap-shaped blue/green leaves with hook (margin) and pointed spines (tip). Central flower stalk with small tubular flowers in clusters.
<i>Aglaonema modestum</i> (Araceae)	Chinese evergreen, Painted drop tongue	Central stem with solid medium green or spotted gray/green leaves; small greenish flowers.
<i>Allamanda cathartica</i> (Apocynaceae)	Allamanda, Yellow allamanda	Ornamental, sprawling, woody climbing shrub with large yellow flowers: opposite lance-shaped leaves: fruitless.
<i>Alocasía</i> spp (Araceae)	Elephant's ear	Erect perennials from running rhizomes; single, long-stemmed, spear-headed varicolored leaves; prominent veins.
<i>Aloe barbadensis</i> (Liliaceae)	Barbados aloe, Curacao aloe	Succulent herb with cluster of narrow fleshy, spinous or coarsely serrated margin leaves, with hook spines on leaf margin. Dense spiked tubular yellow flowers at end of single stalk.

TABLE 7 POISONOUS HOUSEPLANTS AND ORNAMENTALS^a (continued)

Comments and Toxic Principles and Effects	Treatment
Abrin, a plant lectin (taxalbumin) related to ricin in hard seed coat, released when chewed on or otherwise broken. Toxin inhibits cellular protein synthesis.	Ingested whole intact seeds nontoxic in most cases. GI clinical signs; assess dehydration and electrolyte status. Electrolyte replacement therapy in severe cases.
Cardioactive steroids and cardiac glycosides throughout entire plant. Na ⁺ /K ⁺ ATPase inhibition, increased intracellular Ca ²⁺ leading to myocardial excitation, bradycardia, ventricular tachycardia/fibrillation and heart block, hyperkalemia, abdominal distress, vomiting, anorexia, and inactivity.	Symptomatic
Unknown toxin(s) but thought to be a sticky, acrid, irritant latex rather than allergens. Calcium oxalate crystals and unknowns found in all parts, especially rhizomes. Ingestion causes immediate intense pain, local irritation to mucous membranes, excess salivation, swollen tongue and pharynx, diarrhea, and dyspnea. Pets' access to plant associated with rhizomes brought indoors for winter storage.	Symptomatic
Sap contains calcium oxalate crystals; saponins and acrid volatile oil in leaves and seeds. On ingestion, causes dermal and oral mucosal irritation and edema.	Symptomatic
The entire plant contains calcium oxalate crystals. On ingestion, causes oral mucosal irritation and edema.	Symptomatic
Contains plumericin, a GI irritant found in the bark, leaves, fruit, seeds, and sap.	Based on exposure dose (abdominal discomfort, diarrhea, dehydration, and electrolyte imbalance). Symptomatic therapy (rehydration and electrolyte replacement) in severe cases.
Water insoluble calcium oxalate and possible proteinaceous toxins (raphides) in leaves, stems, and tubers.	Burning/painful/inflammatory reaction in mouth on ingestion. Analgesics and/or demulcents may be indicated. Systemic reaction to insoluble calcium oxalate not reported.
Contains anthraquinone glycosides (barbaloin, emodin) and chrysophanic acid in the latex of the leaves; higher concentrations in younger leaves. On ingestion, causes abrupt, severe diarrhea and/or hypoglycemia, with vomiting in some cases.	Symptomatic; control diarrhea and fluid loss.

(continued)

TABLE 7 POISONOUS HOUSEPLANTS AND ORNAMENTALS^a (continued)

Scientific Name (Family)	Common Name	Important Characteristics
<i>Anthurium</i> spp (Araceae)	Anthurium, Flamingo lily, Flamingo flower, Tail flower	Dark green or shiny broad heart-shaped, leathery leaves; a persistent white/scarlet/green spike; flowering, colorful berries.
<i>Arum</i> spp (Araceae)	Italian arum, Black calla, Starch root, Cuckoopint	Stemless plant with large ovate leaves and tuberous roots; showy flower, purple enclosing a spike having red fruits; common houseplant of Europe/Near East origin.
<i>Aucuba japonica</i> (Cornaceae)	Japanese aucuba, Japanese laurel, Spotted laurel	Cultivated as an ornamental and houseplant (large bush) with coarsely toothed, large opposite leaves; purple flowers in panicle at end of branches; scarlet berry, single seed fruit; matures in early winter.
<i>Brunfelsia pauciflora floribunda</i> (Solanaceae)	Yesterday-today-and-tomorrow, Lady-of-the-night	Evergreen shrubs to small trees with alternate, undivided, toothless, thick, rather leathery, lustrous leaves. Winter-blooming; large showy sometimes fragrant flowers, clustered or solitary at the branch ends, with 5-lobed tubular calyx, 5 petals, and funnel-shaped corolla. Fruits berry-like capsules.
<i>Caladium</i> spp (Araceae)	Caladium, Fancy leaf caladium, Angel wings	Perennial herbs with simple, heart-shaped, thin, highlighted veins, variegated leaves; yellow-green spathe; grown from rhizomes.
<i>Cannabis sativa</i> (Cannabaceae)	Mary Jane, Marijuana, Grass, Pot, Hashish, Indian hemp, Reefer, Weed	Annual herb, grown from seeds, ≥6 ft tall. Leaves opposite or alternate, palmately compound with 5–7 linear, coarsely dentate leaflets; small green flowers at tip (male) or along entire length (female) of branch; fruits achenes. Grown for its fiber; legally cultivated under federal license only in most states.
<i>Capsicum annuum</i> (Solanaceae)	Cherry pepper, Chili pepper, Ornamental pepper, Capsicum	Annual shrub; branched, erect stem; dark, glossy, ovate, entire margin leaves; white flowers. Fruits are shiny berries of various colors, shapes, sizes.

TABLE 7 POISONOUS HOUSEPLANTS AND ORNAMENTALS^a (continued)

Comments and Toxic Principles and Effects	Treatment
Native to tropical America (common houseplant); raphides (water-insoluble calcium oxalate and proteinaceous toxins) in leaves and stems.	On ingestion, painful/burning sensation and inflammation of oral cavity. Remove from source; symptomatic treatment helpful, but clinical signs subside over time.
Entire plant contains yet to be identified GI toxin (once thought to be calcium oxalate); dose-dependent mucous membrane irritation, ulcerations, abdominal discomfort, vomiting, diarrhea, and dehydration.	Analgesics for oral mucosal irritation and pain, rehydration, antiemetics, and electrolyte replacement as needed.
Aucubin (acid labile glycoside) found throughout the plant (concentrated in fruit, which is colorful and to which pets are attracted). Large exposure dose required for toxicity (GI discomfort).	None in small dose exposure cases. Rehydration, antiemetics, and electrolyte replacement may be necessary in severely affected cases.
Alkaloid components (atropine, scopolamine, hyoscyamine) found in the flowers, leaves, bark, and roots. On ingestion, animals show tachycardia, dry mouth, dilated pupils, ataxia, tremors, depression, urinary retention, and sometimes coma (deep sedation). Not reported to cause death.	In severely depressed animals, stimulants (respiratory and cardiac), along with supportive therapy recommended.
Calcium oxalate crystals and unknowns found in all parts, especially rhizomes. Ingestion causes immediate intense pain, local irritation to mucous membranes, excess salivation, swollen tongue and pharynx, diarrhea, and dyspnea. Pets' access to plant associated with rhizomes brought indoors for winter storage.	Symptomatic
Leaves, stems, and flower buds of mature plants contain tetrahydrocannabinol (THC) and related compounds. THC concentrations vary with plant variety (1%–6%), parts (female flowers have highest concentrations), processing (extracts have as much as 28%), sex, and growing conditions. Lethal dose for dogs >3 g/kg body wt. Pets' exposure usually from accidental access to this plant being used for in-home treatment of cancer patient or for illegal (in most states) recreational uses by owner. Pets (dogs primarily) show ataxia, vomiting, mydriasis, prolonged depression, tachycardia or bradycardia, salivation, hyperexcitability, tremors, and hypothermia. Death results when vital CNS regulatory centers are severely depressed.	Remove animal from source. Effectiveness of emetics limited by antiemetic effect of THC. Oral tannic acid, activated charcoal, followed by saline cathartics have been recommended. Stimulants (cardiac and respiratory) along with supportive therapy essential in severely depressed animals. Recovery slow at best. <i>See also</i> p 3041.
Capsaicinoids (capsaicin) in the mature fruits, solanine and scopolin in foliage; irritating to the GI tract, with vomiting and diarrhea. Not likely to be lethal.	Symptomatic; irritation relief—cool water irrigation, topical or oral mineral or vegetable oil. Rarely topical anesthetics.

(continued)

TABLE 7 POISONOUS HOUSEPLANTS AND ORNAMENTALS* (continued)

Scientific Name (Family)	Common Name	Important Characteristics
<i>Catharanthus reseus</i> (Apocynaceae)	Madagascar periwinkle, Bigleaf periwinkle, Vinca, Large periwinkle	Perennial herb with milky sap; erect stems with glossy green opposite leaves; solitary rose-pink to white flowers. Cultivated as an ornamental.
<i>Chlorophytum</i> spp (Liliaceae)	Spider plant, St. Bernard's lily, Airplane plant	Rhizomatous herbs with leaves slightly glossy, succulent, narrow, strap-like, green—some with a broad, yellow, or white band down the middle; long, cream, hanging stems with small, white flowers developing into plantlets. Often grown in hanging baskets.
<i>Colchicum autumnale</i> (Liliaceae, Colchicaceae)	Autumn crocus, Crocus, Fall crocus, Meadow saffron, Wonder bulb	Popular house or yard plant, perennial herb, ovoid underground corm covered with brown membrane or scales. Leaves large, lanceolate, basal, ovate, smooth, ribbed, appear in spring and die back before flowering. Flowers tubular, solitary, pale purple or white appearing in fall; fruit a 3-celled ovoid capsule with numerous seeds.
<i>Convallaria majalis</i> (Liliaceae)	Lily-of-the-valley, Conval lily, Mayflower	Herbaceous perennial from slender running rhizome; stem leafless, bearing a 1-sided raceme of nodding white, aromatic, bell-shaped flowers; leaves 2 or 3, basal to 1 ft long. Fruit a red berry but seldom formed.
<i>Cyclamen</i> spp (Primulaceae)	Cyclamen, Snowbread, Shooting star	Herbaceous plants, grown from rhizomes or tubers. Petioled, heart-shaped, deep green intermixed with lighter green coloration (same leaf), serrated leaves; stems upright, with a terminal pink or white butterfly-like flower.
<i>Dieffenbachia</i> spp (Araceae)	Dumbcane	Fairly tall, erect, unbranched, fleshy plant; stem girdled with leaf scars; leaves large, thickly veined, sheath-like petioles, white or yellow spots on blade.

TABLE 7 POISONOUS HOUSEPLANTS AND ORNAMENTALS^a (continued)

Comments and Toxic Principles and Effects	Treatment
Vinca alkaloids (vincristine/vinblastine) throughout the plant inhibit microtubule formation. Toxic exposures lead to pharyngeal pain, GI signs (abdominal pain, severe diarrhea), dehydration, peripheral nerve damage, bone marrow suppression/depression, and cardiovascular damage.	Aggressive supportive and symptomatic therapy essential, with extended monitoring.
More commonly grown for its filtering ability. Pets (especially cats) reach these plants either by climbing or when plantlets fall from mature stems. Unknown toxin(s) found in leaves and plantlets. Vomiting, salivation, retching, and transient anorexia seen in cats within hours of ingestion. Deaths and diarrhea not reported.	Symptomatic
Colchicine and related alkaloids found throughout plant. These alkaloids are heat stable and not affected by drying. Colchicine is used experimentally in genetic investigations, and medically in the treatment of gout in people. It is cumulative and slowly excreted. Milk of lactating animals is a major excretory pathway. Clinical signs include thirst, difficult swallowing, abdominal pain, profuse vomiting and diarrhea, weakness, and shock within hours of ingestion. Death from respiratory failure.	Prolonged course due to slow excretion of colchicine. Gastric lavage; supportive care for dehydration and electrolyte losses (fluid therapy); CNS, circulatory, and respiratory disturbances. Analgesics and atropine recommended for abdominal pain and diarrhea.
Cardiac glycosides (convallarin, convallamarin, convallatoxin), irritant saponins found in leaves, flowers, rhizome, and water in which flowers have been kept. Variable latent period depending on dose. GI signs (vomiting, trembling, abdominal pain, diarrhea), progressive cardiac irregularities (irregular heart beats, AV block), and death. Hyperkalemia in acute cases. Gastroenteritis, petechial hemorrhages throughout.	Aimed at gut decontamination (gastric lavage) and at correcting bradycardia (atropine), conduction defects (phenytoin), and electrolyte imbalance such as hyperkalemia (IV electrolytes). Electrocardiographic and serum potassium monitoring necessary.
Triterpenoid saponins found in tuberous rhizomes cause GI irritation, thereby increasing systemic absorption and severe toxicity. Anorexia, diarrhea, convulsions, and paralysis are observed clinical signs. Pets have greater access to these plants over winter months (both pets and plants are indoors).	Symptomatic
Calcium oxalate crystals and unknown toxic proteins (possibly asparagine or protoanemonin) in all parts, including sap. On ingestion, immediate intense pain, burning, and inflammation of mouth and throat, anorexia, vomiting, and possibly diarrhea, with tongue extended, head shaking, excessive salivation, and dyspnea. Immediate pain limits amount consumed. Death infrequent.	Symptomatic

(continued)

TABLE 7 POISONOUS HOUSEPLANTS AND ORNAMENTALS* (continued)

Scientific Name (Family)	Common Name	Important Characteristics
<i>Digitalis purpurea</i> (Scrophulariaceae)	Foxglove	Erect biennial with simple, petioled (long on lower, short or sessile on upper), alternate, toothed, hairy, ovate to lanceolate leaves. Purple, pink, red, white, or yellow tubular flowers (with spots) in terminal racemes; fruit is a capsule with many seeds.
<i>Dracaena</i> spp (Agavaceae)	Dragon tree	Robust, palm-like houseplant with lance-shaped, thin, variegated, alternate, non-petioled leaves. Yellow, red, or green stripes along leaf margins in some species. Lower leaves are lost, leaf scars remain and clearly demarcated, terminal leaves retained as plant matures.
<i>Epipremnum aureum</i> (Araceae)	Golden pathos, Hunter's robe, Taro vine, Amarillo	Climbing vine with large heart-shaped yellow streaked leaves. Outdoor plants in the tropics, indoor potted plant (leaves are much smaller).
<i>Euphorbia pulcherrima</i> (Euphorbiaceae)	Poinsettia, Christmas flower, Christmas star	Perennial shrub with milky, white sap throughout. Leaves alternate, petioled, distinctly veined, entire or lobed, and conspicuously bright red, pink, or white (terminal leaves), lower leaves remain green. Flowers small and inconspicuous.
<i>Ficus</i> spp (Moraceae)	Weeping fig, Rubber tree, Climbing fig	Numerous species (trees/shrubs/ vines) within the family. Milky sap (leaves, stems) in all. Commonly cultivated as potted and/or indoor landscape houseplants.
<i>Hedera</i> spp (Araliaceae)	Canary ivy, English ivy, Common ivy	Climbing vine (wall cover); leaves with 5 lobes on young and root-free stems; non-lobed leaves (mature sections and root-free stems). Fruits are black berries when mature. Plant escapes cultivation; common houseplants.
<i>Hyacinthus</i> spp (Liliaceae)	Hyacinths	Garden ornamentals that grow from bulbs (close resemblance to onion bulbs) and flower in early spring. Bulbs harvested and stored in fall for replanting in spring.
<i>Ilex aquifolium</i> (Aquifoliaceae)	English holly, European holly	Evergreen shrub with leaves leathery, glossy upper surface, spiny toothed, alternate, and petioled; fruits red to yellow berries with many seeds and aromatic taste.

TABLE 7 POISONOUS HOUSEPLANTS AND ORNAMENTALS* (continued)

Comments and Toxic Principles and Effects	Treatment
Cardiac glycosides (digitoxin, digitalin, digoxin, and others), saponins, and alkaloids found throughout plant. Potency not affected by drying. Generally, acute abdominal pain, vomiting, bloody diarrhea, frequent urination, irregular slow pulse, tremors, convulsions, and rarely death.	Symptomatic
Alkaloids, saponins, and resin found in leaves. Vomiting and severe diarrhea indicative of GI irritation expected. Clinical cases have not been reported.	Symptomatic, to correct fluid and electrolyte imbalance.
Entire plant is poisonous. Contains waterinsoluble calcium oxalate raphides and unknown proteinaeous toxins throughout. Causes immediate intense pain (oral cavity) on chewing any portion of plant.	Oral pain resolves slowly without treatment. In severe cases, demulcents and analgesics may be indicated. Systemic involvement, if any, is not associated with raphide chewing and release of insoluble calcium oxalate.
Milky sap contains unknown toxic principle(s); irritates mucous membranes and causes excessive salivation and vomiting but not death. Toxicity (hybrid species) not supported experimentally. Toxic diterpenes (ingenol derivatives) found in other <i>Euphorbia</i> spp have not been found in this species.	Symptomatic; gastric lavage, activated charcoal, and saline cathartics should be considered.
Furocoumarins, psoralens, ficin, sesquiterpinoid glycoside, and triterpenes are found in sap and implicated (although not clear) in dermatologic toxicity (contact dermatitis) in pets/people.	Symptomatic and supportive care as needed.
Hederin, a saponin found in berries and leaves. Toxin poorly absorbed on ingestion; therefore, limited toxic effects observed. Large exposure dose results in GI effects (abdominal discomfort, diarrhea). Allergic sensitization common in people (contact dermatitis).	Concerns GI-associated problems (dehydration, vomiting, and electrolyte disturbances). Correct dehydration; antiemetics and electrolyte supplementation.
Calcium oxalate crystals and alkaloids (toxic potential yet to be defined) found in bulbs. After ingestion of toxic dose (bulbs), vomiting, diarrhea, and rare deaths reported. Bulbs in storage may be accessible to pets.	Symptomatic
Saponins; an alkaloid (theobromine), triterpene compounds, and unknown compounds with digitalis-like cardiotonic activity have been found in leaves, fruits, and seeds. Abdominal pain, vomiting, and diarrhea seen after ingestion of ≥ 2 berries. Death rare.	Symptomatic (at best)

(continued)

TABLE 7 POISONOUS HOUSEPLANTS AND ORNAMENTALS^a (continued)

Scientific Name (Family)	Common Name	Important Characteristics
<i>Kalanchoe</i> spp (Crassulaceae)	Kalanchoe, Air plant, Cathedral bells	Winter flowering, herbaceous, succulent, nonhardy annuals or perennials. Fleshy, serrate or crenate, opposite, petioled leaves. Bright red, orange, or pink flowers in umbel. Stems become woody and untidy with age.
<i>Lilium longiflorum</i> , <i>L. tigrinum</i> (Liliaceae)	Easter lily, Trumpet lily	Plants grown from bulbs; leaves alternate or whorled, sessile, linear or lanceolate blades; large showy funnel-form flowers. Fruits capsules with numerous, flat seeds.
<i>Narcissus</i> spp (Amaryllidaceae)	Daffodils, Amaryllis, Naked lady lily	Plant grown from bulb with leaves arising from ground. Flower(s) white or yellow arising from stalk. Plant grows from bulb (extends partially above ground). Flowers of various colors, red, pink, and white most common.
<i>Persea americana</i> (Lauraceae)	Avocado pear, Alligator pear	Trees or shrubs with long branches arising from terminal buds, widely cultivated for its fruits. Three commonly cultivated races (Mexican, Guatemalan, and West Indies). Leaves ovate-elliptical, entire, alternate, veined, dark-green above and paler below, papery to the feel. Flowers inconspicuous, yellow-green in axillary or terminal panicles; fruit berry, ovoid to pyriform in shape with thick, leathery, glossy dark green skin over lime-green to yellow flesh and a smooth, ovoid, solitary seed.
<i>Philodendron</i> spp (Araceae)	Philodendron	Climbing vines with aerial roots; leaves (major attraction as a houseplant) are large, unlobed or pinnately lobed and heart-shaped; rarely flowering.
<i>Phoradendron flavesces</i> (Viscaceae)	Mistletoe	Perennial parasitic shrub that grows on deciduous trees. Evergreen, ovoid, opposite leaves on round, highly branched, green stem. White berries with single seed. Brought into homes during Christmas season.
<i>Rhododendron</i> spp (Ericaceae)	Azalea, Rhododendron	Evergreen or deciduous shrub with simple, alternate, entire leaves; funnel-shaped flowers in terminal umbel-like clusters or solitary and of various colors; fruits are capsules with many seeds.

TABLE 7 POISONOUS HOUSEPLANTS AND ORNAMENTALS^a (continued)

Comments and Toxic Principles and Effects	Treatment
Cardiac glycosides found in leaves. Within hours of ingesting toxic dose, depression, rapid breathing, teeth grinding, ataxia, paralysis, opisthotonos (rabbit), and death (rat).	Symptomatic; atropine has been effective in rabbits.
Unknown toxin found throughout plants. Renal failure in cats 2–4 days after ingestion. Not reported toxic to other species. Vomiting, depression, loss of appetite within 12 hr after ingestion. Increased creatinine, BUN, phosphorus, and potassium indicate toxicity.	Emetics, activated charcoal, saline cathartic, and nursing care—as for renal failure—within hours of ingestion. Delayed treatment is associated with poor prognosis.
Bulbs are poisonous; contain lycorine and related phenanthridine alkaloids. If small dose ingested, few or no clinical signs; if large-dose exposure, vomiting, abdominal discomfort, diarrhea, dehydration, and electrolyte imbalance.	Most exposures result in limited toxic responses and resolve without treatment. In large-dose exposure, symptomatic treatment with rehydration, antiemetics, electrolyte replacement.
All above-ground parts (leaves in particular) reported toxic to cattle, horses, goats, rabbits, canaries, ostriches, and fish. Responsible toxin a monoglyceride. Oil found in fruits used for cosmetic purposes. Toxicity associated with noninfectious agalactia (cattle, rabbits, goats), pulmonary congestion, cardiac arrhythmia, submandibular edema, acute death (rabbits, caged birds, goats), respiratory distress, generalized congestion, subcutaneous edema, and hydropericardium (suggestive of cardiac failure [caged birds]). In caged birds, clinical signs may be seen within 24 hr (usually after ≥12 hr), with death 1–2 days after exposure.	Primarily symptomatic and supportive (see p 2964).
Calcium oxalate crystals and unidentified proteins throughout entire plant. On ingestion, immediate pain, local irritation to mucous membranes, excessive salivation, edematous tongue and pharynx, dyspnea, and renal failure. Excitability, nervous spasms, convulsions, and occasional encephalitis reported in cats.	Symptomatic
Amines (β -phenylethylamine, acetylcholine, choline, and tyramine), toxic proteins (viscotoxins), and unknowns in all parts. Vomiting, profuse diarrhea, dilated pupils, rapid labored breathing, shock, and death from cardiovascular collapse within hours of ingesting toxic dose.	Symptomatic
Andromedotoxins (grayanotoxins) found in all parts, including pollen and nectar. Within hours of ingestion of toxic dose (1 g/kg), salivation, lacrimation, vomiting, diarrhea, dyspnea, muscle weakness, convulsions, coma, and death. Signs may last several days, but toxin is not cumulative.	Symptomatic; gastric lavage, activated charcoal, saline cathartics, calcium injection, and antibiotics to control possible pneumonia suggested.

(continued)

TABLE 7 POISONOUS HOUSEPLANTS AND ORNAMENTALS^a (continued)

Scientific Name (Family)	Common Name	Important Characteristics
<i>Sansevieria</i> spp (Agavaceae)	Sansevieria, Snake plant, Mother-in-law's tongue	Hardy, succulent houseplant. Leaves erect, elongate, lanceolate, and flat or cylindrical, dark green with or without a yellow stripe along the margins, and horizontal gray bands throughout; many yellow star-like flowers on tall central raceme or spike.
<i>Schefflera</i> spp (Araliaceae)	Schefflera, Umbrella tree	Fast-growing evergreen with glossy, palmately compound leaves that hang and spread, appearing like an umbrella. Depending on the species, leaflets increase with plant maturity and become more compact; veins pronounced; margins entire to slightly crenate.
<i>Solanum pseudocapsicum</i> (Solanaceae)	Jerusalem cherry	Shrub with simple, lanceolate, entire or slightly serrated leaves. Small, star- shaped white flowers. Ripe fruits are red, shiny berries with many white seeds.
<i>Taxus</i> spp (Taxaceae)	Yew	Evergreen tree or small erect shrub with alternate, needle-like, glossy (upper surface), dull (lower surface) leaves. Seeds (generally one per fruit) black- brown or green, nearly enclosed in a cup-shaped, fleshy, red covering (aril).
<i>Zamia pumila</i> (Zamiaceae)	Coontie, Florida arrowroot, Seminole bread, Cycad	Palm-like plant with thick underground fleshy, tuberous stem from which grow few pinnately compound, palm-like leaves ~2 ft long; cones containing inch-long, shiny, orange-red seeds.

^a Images for many of the plants described here, as well as for plants of Australia, the Caribbean, and South Africa, are available online at www.merckvetmanual.com.

TABLE 7 POISONOUS HOUSEPLANTS AND ORNAMENTALS^a (*continued*)

Comments and Toxic Principles and Effects	Treatment
Hemolytic saponin and organic acids found in leaves and flowers. Vomiting, salivation, diarrhea, and hemolysis related to GI activity of these compounds.	Symptomatic; fluids and electrolytes may be necessary.
Oxalate found in the leaves. Mucous membrane irritation, salivation, anorexia, vomiting, and if severe enough, diarrhea.	Symptomatic
Solanocapsine and related alkaloids found in leaves and fruits. Anorexia, abdominal pain, vomiting, hemorrhagic diarrhea, salivation, progressive weakness or paralysis, dyspnea, bradycardia, circulatory collapse, dilated pupils, and convulsions reported.	Symptomatic; gastric lavage, activated charcoal, electrolytes and fluids, and anticonvulsants suggested.
The alkaloids (taxines and ephedrine), cyanide, and volatile oils found throughout plant except the fleshy aril. Nervousness, trembling, ataxia, dyspnea, collapse; bradycardia progressing to cardiac standstill and death without struggle. Empty right side of heart; dark, tarry blood in left side of heart; limited nonspecific postmortem lesions.	Symptomatic at best; usually futile once clinical signs appear. Atropine may be helpful.
The glucoside cycasin and its aglycone methylazoxymethanol (a colon-specific carcinogen in mice) found in leaves, seeds, and stem. Ingestion associated with hepatic and GI disturbances and ataxia. Clinical signs are persistent vomiting, diarrhea, abdominal pain, depression, and muscular paralysis. A neurologic condition characterized by hindleg paralysis (hyperextension followed by incomplete extension) has been reported in cattle.	No specific therapy; IV fluids and symptomatic care recommended.

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: SPRING AND FALL		
<i>Allamanda cathartica</i> , <i>A blanchetti</i> (Apocynaceae) Allamanda, Yellow allamanda, Golden trumpet, Purple allamanda	Native to tropical America (2 cultivated taxa in North America); indoors and as ornamentals.	Sheep, cattle, and goats
<i>Cicuta</i> spp Water hemlock	Open, moist to wet environments; throughout North America	All
<i>Hymenoxys odorata</i> Bitterweed	Roadways, lakebeds, flooded areas, overgrazed range; southwest	Sheep, rarely cattle
<i>Hymenoxys richardsonii</i> Pingue, Colorado rubber weed	Arid foothills (6,000–8,000 ft [1,800–2,400 m]); western	Sheep, cattle, goats
<i>Oxalis</i> spp, <i>O corniculata</i> (Oxalidaceae) Wood sorrel, Creeping lady's sorrel, Creeping yellow wood sorrel	Herb/ornamentals found as weeds, growing from rhizomes/bulbs in fields and/or grazing pasture; worldwide	Sheep, rarely cattle

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DAINGEROUS SEASON: SPRING AND FALL		
Perennial, evergreen shrub, climbing; leaves simple, whorled; leathery, margins entire, axillary glands at base; large showy, yellow or purple petal flowers; fruit is spiny capsule with numerous winged seeds.	The entire plant contains alkyliridoid-type terpinoids (allamandin, qallamandin, allamandacin), iridoids plumericin and plumieride, and little cardiotoxin. GI irritants in all parts (highest concentrations in the sap and roots). On ingestion, causes excess salivation, ruminal atony, abdominal cramps, diarrhea, dehydration, and electrolyte imbalance. Little cardiotoxic effects and no deaths. Lethal dose (fresh foliage) in cattle is 30 g/kg body wt.	Supportive, antidiarrheals
White flower, umbels. Veins of leaflets ending at notches. Stems hollow except at nodes. Tuberous roots from chambered rootstock.	Resinoids (cicutoxin, cicutol) in roots, stem base, young leaves. Toxicity retained when dry, except in hay. Rapid onset of clinical signs, with death in 15–30 min. Salivation, muscular twitching, dilated pupils. Violent convulsions, coma, death. Poisoning in people common.	Sedatives to control spasm and heart action. Prognosis good if alive 2 hr after ingestion.
Multibranched annual or perennial up to 2 ft high. Yellow flower head. Leaves divided into narrow glandular segments.	Sesquiterpene lactone (hymenovin) in fresh or dry plant. Salivation, vomiting, green nasal discharge, depression, anorexia, abdominal pain. Lesions include inflammation of GI tract, foreign body pneumonia, renal degeneration.	Toxin cumulative. Avoid overgrazing. Remove from pasture.
Perennial herb. Leaves bright green, divided into narrow glandular segments.	Same as for <i>H odorata</i> (above).	Same as for <i>H odorata</i> .
Annual/perennial with palmately compound leaves with 3 leaflets on erect or ascending stem. Inflorescence cymes or umbel or solitary flower; fruits are capsules with many seeds and basal ariels.	High oxalate contents throughout. Acute, subacute, or chronic manifestation after chronic ingestion. Clinical signs—progression from depression, weakness, labored respiration to prostration, coma, and death in 1–2 days in acute cases. Chronic cases—weight loss, anorexia, polyuria, edema, increased BUN and creatinine levels, failure to concentrate urine, presence of oxalate crystals in urine sediments, and renal failure.	Parenteral calcium solution. Supportive care to allow for tubular regeneration.

(continued)

TABLE 8 POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: SPRING AND FALL (continued)		
<i>Zephyranthes atamasco</i> (Amaryllidaceae) Atamasco lily, Rain lily, Zephyr lily, Easter lily	Ornamental, commonly grows from bulbs in low woods and wet meadow areas.	Horses, cattle, and indoor pets (cats)
DANGEROUS SEASON: SPRING		
<i>Baptisia</i> spp (Papilionoideae, Leguminosae, Fabaceae) False indigo, Wild indigo, Rattle weed, Yellow indigo, Indigo weed	Open woods in Eastern North America on clay, loam, and sandy soils	Horses, cattle, goats
<i>Caesalpinia</i> spp (Leguminosae) Nikals, Grey nicker bean	Grown in the tropics in dry, open shrub or lowland rain forest. Found in southwestern USA. Ornamentals cultivated in warmer areas.	Cattle, sheep, probably horses
<i>Nolina texana</i> Sacahuista, Beargrass	Open areas on rolling hills and slopes; southwest USA and Mexico	Cattle, sheep, goats

TABLE 8**POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)**

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: SPRING AND FALL (continued)		
Basal leaves with star-shaped white flowers turning pink on fading.	Phenanthridine (lycorine, tazet-tine) and other alkaloids primarily in the bulbs but also in the leaves and flowers. Anticholinergic-type effects (inhibitor of protein synthesis, decreases heart rate, and cardiac abnormalities) in cats. Vomiting, excess salivation, bloody diarrhea (dehydration and electrolyte imbalance), seizures, cardiac function changes, and dermatitis.	Prompt resolution of dermatologic signs with discontinued exposure. Supportive care—antiemetics, antidiarrheals, and electrolyte replacement. Rarely lethal.
DANGEROUS SEASON: SPRING		
Herbaceous perennials, branched solitary stem, palmately compound sessile/short petiole, 3-leaflet leaves; terminal or axillary raceme inflorescence. Flowers with variably colored petals; legumes stipitate with one to many seeds. Plants black-gray or silvery gray when dry in the field or as hay.	Contains quinolizidine alkaloid cystisine, pyridine alkaloids anagryne and baptifoline, and other related nicotine-like alkaloids. Interact with nicotinic, muscarinic, and acetylcholinergic receptors. On ingestion, causes severe diarrhea in cattle, decreased appetite, excess salivation, incoordination, and tremors. Fetal anomalies can be produced.	Remove animals from plant source. Symptomatic and supportive care.
Perennial tree, shrub, or herb armed with thorns, erect or climbing stem, 2 pinnately compound leaves, terminal racemes, showy yellow to orange or red flowers, legumes ovate with 2 to many seeds.	Gallotannins (30%–50%), phytohemagglutinins in fruit and flowers and diterpenoids pulcherralin and caesalpin in the leaves. Within a few hours of ingestion, animals show vomiting, ± bloody diarrhea, abdominal discomfort, and dehydration. Not reported to cause death.	Supportive care—IV fluids, electrolytes, antiemetics, and antidiarrheals.
Perennial with many clustered, long narrow leaves. Stem mostly underground. Several flower stems with many small, white flowers in clusters.	Unidentified hepatotoxin (buds, flowers, fruit). Photosensitization, anorexia, icterus, prostration. Dark urine, yellowish discharge from eyes, nostrils. Lesions include hepatic and renal degeneration, GI inflammation.	Remove animals from area where plant grows during blooming season. Oral daily zinc oxide (not zinc sulfate) supplementation at 30 mg/kg body wt appears promising. (See also PHOTSENSITIZATION, p 976).

(continued)

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DAANGEROUS SEASON: SPRING (continued)		
<i>Peganum harmala</i> African rue	Arid to semiarid ranges; western USA	Cattle, sheep, probably horses and camels
<i>Phytolacca americana</i> Pokeweed, Poke	Disturbed rich soils such as recent clearings, pastures, waste areas; eastern half of USA	Pigs, cattle, sheep, horses, people
<i>Quercus</i> spp Oaks	Most deciduous woods; throughout North America	All grazing animals, mostly cattle
<i>Sarcobatus vermiculatus</i> Greasewood, Black greasewood	Alkaline or saline bottom soils, not in higher mountains; arid west. Dangerous season spring; may be year-round.	Sheep, cattle
<i>Xanthium</i> spp Cocklebur	Fields, waste places, exposed shores of ponds or rivers; throughout North America. Dangerous season spring and occasionally fall.	All animals, more common in pigs

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: SPRING (continued)		
Multibranched, leafy, perennial, bright green, succulent herb. Leaves divided. Flowers white, single.	Related β -carboline indole alkaloids (seeds, leaves, stems; seeds more toxic). Anorexia, hindleg weakness, knuckling of fetlock, listlessness, excess salivation, subnormal temperature, pollakiuria. Lesions include gastroenteritis, with hemorrhages on heart and under liver capsule.	Unpalatable. Eaten only under drought conditions. General supportive care most helpful.
Tall (to 9 ft), glabrous, green, red-purple, perennial herbs. Berries black-purple, staining, in drooping racemes.	Oxalic acid, a saponin (phytolaccatoxin), and an alkaloid (phytolaccin) in all parts; roots most toxic. Vomiting, abdominal pain, bloody diarrhea, hemolytic anemia, drop in production (dairy cattle). Terminal convulsions, death from respiratory failure. Lesions include ulcerative gastritis, mucosal hemorrhage, dark liver.	No specific remedy for intoxication. Supportive and symptomatic care helpful. Monitor for hypotension and other cardiac effects. Oils and protectants (GI tract). Dilute acetic acid PO, stimulants. Blood transfusion (hemolytic anemia).
Mostly deciduous trees, rarely shrubs, with 2–4 leaves clustered at tips of all twigs. Diverse leaf shape. Acorn fruiting body.	Gallotannin thought to be the toxin (young leaves and swollen or sprouting acorn). Anorexia, rumen stasis, constipation, followed by dark tarry diarrhea, dry muzzle, frequent urination, rapid weak pulse, death. Lesions include perirenal edema, nephrosis, gastroenteritis.	Diet must consist of >50% oak buds and young leaves for a period of time. Increased BUN with diet history diagnostic. Treatment symptomatic. Oral ruminantotics helpful. See also p 3152.
Large deciduous shrub with spiny stems. Fleshy, alternate, round in cross-section. Flowers inconspicuous.	Oxalates (sodium and potassium) 10%–15% dry weight (leaves primarily, less so in stems and fruits). Dyspnea, weakness, depression, some salivation, atony of GI tract, coma, death (neurologic effects and renal failure). Hyperkalemia, hypocalcemia, increased BUN. Lesions include hemorrhage and edema of rumen wall, ascites, swollen kidneys (renal tubular necrosis and dilation).	Toxic when large quantity consumed in short time. Do not allow hungry animals to graze plant. Parenteral calcium solution offers temporary relief but relapses.
Coarse annual herb. Fruit covered with spines, 2-beaked, with 2 compartments.	Carboxyatractyloside (seeds and young seedlings). Anorexia, depression, nausea, vomiting, weakness, rapid weak pulse, dyspnea, muscle spasms, convulsions. Lesions include GI inflammation, acute hepatitis, nephritis.	Seedlings or grain contaminated with seeds. Oils and fats PO may be beneficial; parenteral glucose and bicarbonate are reported helpful; warmth, stimulants IM.

(continued)

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: SPRING (continued)		
<i>Zygadenus</i> spp Death camas, Meadow death camas, Grassy death camas	Foothill grazing lands, occasionally boggy grasslands, low open woods; throughout North and Central America	Sheep, cattle, horses
DANGEROUS SEASON: SPRING AND SUMMER		
<i>Aesculus</i> spp Buckeye	Woods and thickets; eastern USA and California	All grazing animals
<i>Amianthium muscaetoxicum</i> Fly poison, Stagger-grass, Crow poison, Gray fly poison	Open woods, fields, and acid bogs; eastern USA	All grazing animals
<i>Delphinium</i> spp Larkspurs	Either cultivated or wild, usually in open foothills or meadows and among aspen; mostly western USA. Dangerous season spring and summer, also seeds in fall.	All grazing animals, mostly cattle; sheep are somewhat resistant.
<i>Descurainia pinnata</i> Tansy mustard	Dense stands especially in wet years; arid southwest	Cattle

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: SPRING (continued)		
Perennial, bulbous, unbranched herbs with basal, flat, grass-like leaves. Flowers greenish, yellow, or pink; in racemes or panicles. No onion odor.	Cevanine-type veratrum azasteroid alkaloids, steroidal alkaloids, glycoalkaloids, and ester alkaloids (all parts). Salivation, vomiting, muscle weakness, ataxia or prostration, fast weak pulse, coma, death (central respiratory depression). No distinctive lesions.	Seeds most toxic. Leaves and stems lose toxicity as plant matures. Atropine sulfate and picrotoxin SC.
DANGEROUS SEASON: SPRING AND SUMMER		
Trees or shrubs. Leaves opposite and palmately compound. Seeds large, glossy brown, with large white scar.	Glycoside, aesculin; also alkaloids and saponins in all parts, especially seeds and leaves. Depression, incoordination, twitching, paralysis, inflammation of mucous membranes.	Young shoots and seeds especially poisonous. Treatment only in severe cases. Stimulants and purgatives. Prevent access to toxic plant. Recovery in days. Rarely fatal.
Bulbous perennial herb. Leaves basal, linear. White flowers in a compact raceme, the pedicels subtended by short, brownish bracts.	Unidentified alkaloid, similar to those with <i>Zygadenus</i> (all parts). Salivation, vomiting, rapid and irregular respiration, weakness, death from respiratory failure.	No practical treatment. Especially dangerous for animals new to pasture. Keep animals well fed.
Annual or perennial erect herbs. Flowers each with 1 spur, in racemes. Perennial with tuberous roots. Leaves palmately lobed or divided.	Polycyclic diterpenoid alkaloids (eg, delphinine) in all parts, fresh or dry. Straddled stance, arched back, repeated falling, forelegs first. Constipation, bloat, salivation, vomiting. Death from respiratory and cardiac failure. Most often no lesions.	Young plants and seeds more toxic. Toxicity decreases with maturity. Antidote physostigmine rather than atropine.
Annual to 2 ft tall, stem and leaves covered with fine pubescence. Leaves alternate, deeply pinnately dissected. Inflorescence on elongated raceme. Flower small with 4 spreading yellow to yellow-green petals. Fruit is copula with 2 carpels and long waxy seeds in 2 rows.	Toxic principle unknown; must be grazed over relatively long period. Partial or complete blindness, inability to use tongue or swallow, "paralyzed tongue," "blind staggers," wandering, head pressing, emaciation, death if not treated.	Administer 2–3 gal. (8–12 L) water bid with stomach tube. Include nourishment if animal weak. Prognosis good if treatment started early. Possibly mustards cause same condition.

(continued)

TABLE 8 POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA* (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: SPRING AND SUMMER (continued)		
<i>Lantana</i> spp Lantana	Ornamentals and wild; in lower coastal plain of southeast USA, and southern California	All grazing animals except horses
<i>Senna obtusifolia</i> Coffeepod, Sicklepod	Found in cultivated (corn, soybean, or sorghum) and abandoned fields, along fences, roadsides; naturalized in eastern USA	All grazing animals, mostly cattle, and poultry (see p 2861)
<i>Senna occidentalis</i> Coffee senna, Coffee weed, Styptic weed, Wild coffee	Common along roadsides, waste areas and pastures; naturalized in eastern USA	Cattle, horses, chickens, goats, sheep, rabbits
<i>Tetradymia</i> spp Horsebrush	Arid foothills and higher desert and sagebrush ranges, dense stands along trails; western USA	Sheep

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: SPRING AND SUMMER (continued)		
Shrubs. Young stems 4-angled. Leaves opposite. Flowers in flat-topped clusters, yellow, pink, orange, or red. Berries black.	Triterpenes (lantadene A and B) and unknowns in all parts, especially leaves and green berries. Anorexia, jaundice, watery feces, photosensitization. Lesions include degenerative changes in liver and kidneys. Death due to liver insufficiency, renal failure, myocardial damage.	Remove plants from pasture (herbicide 2,4-D susceptible). Keep animals out of light sources after eating plant.
Annual shrub frequently found in same fields as <i>S. occidentalis</i> . Distinguishing features include leaflets fewer in number and more rounded. Seed pods long, round to 4-sided and more curved. Seeds shiny, brown, and rhomboid.	Toxic principles thought to be same as in <i>S. occidentalis</i> . Clinical signs, although similar, less severe with <i>S. obtusifolia</i> .	Treatment ineffective in down animals; salvaging most economic. Heat labile toxins not known to persist as residue. Meat from affected animals should be safe for human consumption.
Annual herb >3 ft tall, with glandular, alternate pinnately compound leaves (8–12 ovate to lanceolate leaflets, terminal pair largest). Flowers are yellow, axillary, solitary, or in short racemes. Long, flat, straight to slightly curved pods with clearly outlined seed contents. Of the pods, seeds, and wilted foliage, seeds are most toxic.	Anthraquinones (emodinyglycosides and oxymethylantraquinone), chrysarobin and lectin (toxalbumins), and alkaloids are associated with GI dysfunction and myodegeneration. Afebrile, ataxic, with diarrhea and coffee-color urine, recumbent but eat and are alert shortly before death. Increased serum CK and isocitric dehydrogenase activities; hyperkalemia and myoglobinuria frequent. Lesions include cardiac and skeletal muscle degeneration. Congestion, fatty degeneration, and centrilobular necrosis (liver) in addition to tubular degeneration (kidneys) also reported. Death probably due to hyperkalemic heart failure.	No specific treatment known. Symptomatic and supportive care essential. Although gross lesions similar to those of vitamin E/ selenium deficiency, this therapy is contraindicated. Mineralocorticoid therapy may facilitate potassium excretion. Remove animals from source. Salvaging for economic reasons (see <i>Senna obtusifolia</i> , above).
Shrubs with yellow flowers in spring, not later. Leaves spiny, silvery white. Early deciduous.	Furanoeremophilanes (tetradymol and others). Photosensitization, "bighead," loss of hair and wool, skin ulcerations, blindness, secondary infections. Lesions include dermal necrosis and edema, hepatic and renal degeneration. Abortions may occur.	Photosensitization seen with concurrent ingestion of other green forages. Remove animals from plant source and sunlight. Antihistamines, topical antibiotics, and parenteral corticosteroids beneficial. Recovery slow and possibly incomplete.

(continued)

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
-----------------------------	--------------------------	------------------

DANGEROUS SEASON: SPRING AND SUMMER (continued)

<i>Veratrum</i> spp False hellebore, Skunk cabbage	Low, moist woods and pastures, and high mountain valleys; western USA	Sheep, cattle
--	---	---------------

DANGEROUS SEASON: SUMMER AND FALL

<i>Acer rubrum</i> Red maple	Moist land and swamps; eastern	Horses
---------------------------------	--------------------------------	--------

<i>Apocynum</i> spp Dogbanes	Open woods, roadsides, fields; throughout North America	All
---------------------------------	---	-----

<i>Centaurea repens</i> Russian knapweed	Waste areas, roadsides, railroads, and overgrazed rangeland; not common in cultivated or irrigated pastures; mostly western and upper midwestern USA	Horses
---	--	--------

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: SPRING AND SUMMER (continued)		
Erect herbs. Leafy throughout, leaves large and plaited. Flowers small and white or greenish.	Steroidal alkaloids. Vomiting, excess salivation, cardiac arrhythmia, bradycardia, dyspnea, muscle weakness and paralysis, coma, congenital cyclops in lambs from ewes exposed to <i>V californicum</i> .	Respiratory and heart stimulants.
DANGEROUS SEASON: SUMMER AND FALL		
A large tree at maturity. Leaves opposite, 2–6 in. across, palmately 3- or 5-lobed each, roughly triangular, and coarsely toothed. Red to yellow polygamous flowers. Fruit, a pair of 1-seeded winged units connected at base.	Unknown toxic principle(s) in wilted leaves. Methemoglobinemia, Heinz body anemia, and intravascular hemolysis; weakness, polypnea, tachycardia, depression, icterus, cyanosis, brownish discoloration of blood and urine.	Not common. Methemoglobinemia a prognostic indicator. Isotonic fluids, oxygen, and blood transfusion can be helpful. Methylene blue therapy not rewarding. Early ascorbic acid treatment essential for recovery.
Erect, branching, perennial herb with milky sap arising from creeping underground root stock. Leaves opposite. Flowers white to greenish white in terminal clusters. Fruit long, slender, paired, with silky-haired seeds.	A resinoid and glucoside with some cardioactivity found in leaves and stems of green or dry plants. Increased temperature and pulse, dilated pupils, anorexia, discolored mucous membranes, cold extremities, death.	Symptomatic (cardio-toxin) IV fluids and gastric protectants suggested.
Perennial weed with slender rhizomes. Stems erect and well branched. Leaves pinnately lobed to entire, not spiny, narrowed basally but not petioled and of decreasing length up the plant. Thinly pubescent or glabrous. Blue, pink, or white flowers. One-seeded fruit with whitish, slightly ridged attachment scar.	Unidentified alkaloid in fresh or dried plant. Chronic exposure, acute onset of signs. Inability to eat or drink, facial dystonia, chewing, yawning, standing with head down, severe facial edema, gait normal, head pressing, aimless walking or excitement most severe the first 2 days, become static thereafter. Death from starvation, dehydration, aspiration pneumonia.	More toxic than <i>C solstitialis</i> (below) but with similar pathology and prognosis. Some relief with massive doses of atropine but not an effective treatment. Euthanasia recommended.

(continued)

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
 DANGEROUS SEASON: SUMMER AND FALL (continued)		
<i>Centaurea solstitialis</i> Yellow star thistle, Yellow knapweed	Waste areas, roadsides, pastures; mostly western	Horses
<i>Eupatorium rugosum</i> White snakeroot	Woods, cleared areas, waste places, usually the moister and richer soils; eastern USA	Sheep, cattle, horses
<i>Hypochaeris radicata</i> Flatweed, Cat's-ear, Gosmore	Native to the Mediterranean and South America; widely distributed in the USA—Pacific states, eastern/ southeastern USA	Horses
<i>Oxytenia acerosa</i> , <i>Iva acerosa</i> Copperweed	Arid, alkaline soils in foothills, sagebrush plains; western USA	Cattle, sheep
<i>Perilla frutescens</i> Perilla mint, Beefsteak plant	Ornamental originally from India, escaped to moist pastures, fields, roadsides, and waste places; southeastern USA	Cattle primarily, horses and other livestock susceptible

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: SUMMER AND FALL (continued)		
Annual weed. Leaves densely covered with cottony hair. Terminal spreading cluster of bright yellow flowers with spines below. Branches winged.	Unidentified alkaloid. Involuntary chewing movements, twitching of lips, flicking of tongue. Mouth commonly held open. Unable to eat; death from dehydration, starvation, aspiration pneumonia.	Horses graze because of lack of other forage. Extended period of consumption essential for toxicity. Liquefactive necrosis of substantia nigra and globus pallidus (brain) pathognomonic. No treatment. Euthanasia recommended.
Erect perennial herb. Tremetol leaves, opposite, simple, serrated. Flowers small, white, and many. Often grows in large patches.	Complex benzyl alcohol (tremetol in leaves and stems). Excreted via milk; cumulative. Weight loss, weakness, trembling (muzzle and legs) prominent after exercise, constipation, acetone odor, fatty degeneration of liver, partial paralysis of throat, death in 1–3 days.	"Milk sickness" or "trembles." Treatment nonspecific and symptomatic. Heart and respiratory stimulants and laxative may be necessary. Remove animal from access to plant, discard milk (hazardous to people).
Perennial herb with viscid sap, stemless. Simple, serrated to lobed, basal, alternate leaves. One to several bright yellow flowers per plant.	Unknown; associated with but not proven cause of a neurologic condition in horses—stringhalt (hypermetria/hyperflexion of pelvic limb) in dry years. Sudden onset of abnormal gait; flexion/delayed extension of hocks, knuckling of carpal joints, laryngeal hemiplasia; spontaneous recovery possible, but condition could be permanent.	Tranquilizers, sedatives, mephenesin, and thiamine (questionable effectiveness); longterm phenytoin therapy seems helpful. Treatment with baclofen also reported helpful. Surgery (pelvic tenotomy of the lateral digital extensors) reported helpful.
Tall, annual/perennial herb with narrow leaflets. Flowers in many heads resembling goldenrod.	Unknown (pseudoguaianolide sesquiterpene lactones found in species—consistent clinical signs with these toxins); all above-ground parts, green or dry. Metabolic disease, anorexia, marked depression, weakness, coma; death without struggle within 1–3 days.	No specific treatment. Supplement diet or change pasture.
Annual, freely branched, squared stems. Opposite, purple or green, coarsely serrated leaves. White to purple flowers. Strong pungent odor when crushed.	Green or dry, 3-substituted furans (perilla ketone, egomaketone, isoegomaketone). Signs 2–10 days after exposure include dyspnea (especially on exhaling), open-mouth breathing, lowered head, reluctance to move, death on exertion. Lesions include pulmonary emphysema and edema.	Treatment ineffective once clinical signs severe. Parenteral steroids, antihistamines, and antibiotics may help. Handle gently (prevents exertion and death). Avoid/limit grazing during flowering and fruiting period.

(continued)

TABLE 8 POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: SUMMER AND FALL (continued)		
<i>Prosopis glandulosa</i> Mesquite	Dry ranges, washes, draws; southwest	Primarily cattle, also goats; sheep resistant
<i>Robinia pseudoacacia</i> Black locust, False acacia, Locust tree	Open woods, roadsides, pinelands, on clay soils preferably; eastern USA	All grazing animals, mostly horses
<i>Rumex crispus</i> Curly dock, Dock, Sorrel	Commonly found on acid or sterile, graveled, seasonally moist soils of waste places, pastures, and fields throughout USA	Cattle, sheep
<i>Solanum</i> spp Nightshades, Jerusalem cherry, Potato, Horse nettle, Buffalo bur	Fence rows, waste areas, grain and hay fields; throughout North America	All

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: SUMMER AND FALL (continued)		
Perennials, deciduous shrub or small tree with smooth or furrowed gray bark, paired spines. Leaves divided. Legume pod long, constricted between seeds.	Unknown principle in the beans. Chronic wasting with rumen atony, excess salivation, continual chewing. Partial paralysis of tongue, facial muscle tremor, submandibular edema, anemia. Lesions include emaciation, small firm kidneys and liver, gastroenteritis, filled rumen.	High sucrose content of beans alters rumen microflora, inhibiting cellulose digestion and B vitamins synthesis if grazed for extended period.
Tree or shrub. Deciduous, alternate, pinnately compound (>10 elliptic to ovate leaflets) leaves. Pair of spines at base of each leaf. Flowers in loose, fragrant, white to cream, drooping racemes. Flattened, brown pods containing 4–8 seeds.	The glycoside robinin, a lectin (hemagglutinin), and the phytotoxins robin and phasin found throughout plant, although flowers have been suggested as the toxic principles. Diarrhea, anorexia, weakness, posterior paralysis, depression, mydriasis, cold extremities; frequently laminitis and weak pulse. Death infrequent; recovery period extensive. Postmortem lesions restricted to GI tract.	Laxatives and stimulants suggested. Treatment symptomatic.
Perennial herb with erect stems, 3–4 ft tall. Leaves alternate, lanceolate to elliptic, finely crisped margins, base obtuse to cuneate, petioles form sheath around stem. Flowers small, numerous, greenish, in long terminal panicles; fruit an achene, papery 3-winged, with lustrous brown seeds.	Oxalic acid and soluble oxalate in leaves, stem, and seeds. Acute course (hypocalcemia, labored breathing, anorexia, depression, muscle fasciculation, tremor, weakness, teeth grinding, pulmonary edema, tetany, seizure, recumbency, and prostration); subacute (hypocalcemia, altered kidney function) or chronic course (renal fibrosis, renal insufficiency, and urolithiasis). Hemorrhage, edema (rumen and abomasal walls), and ascites (intestinal mucosa) seen in toxic cases. Death resulting from shock and hemorrhagic rumenitis.	In acute cases, death is too rapid for any treatment. Symptomatic and supportive care can be helpful. Remove animals from source. Calcium IV to correct hypocalcemia is ineffective. Give lime water to precipitate oxalate and prevent absorption. Allow animals to develop tolerance to oxalate by exposure to small amounts over time. Do not allow animals to graze pasture or offer hay highly contaminated with oxalate-producing plants.
Fruits small; yellow, red, or black when ripe; structurally like tomatoes; clustered on stalk arising from stem between leaves.	Glycoalkaloid solanine (leaves, shoots, unripe berries). Acute hemorrhagic gastroenteritis, weakness, excess salivation, dyspnea, trembling, progressive paralysis, prostration, death.	Pilocarpine, physostigmine, GI protectants. Seeds may contaminate grain.

(continued)

TABLE 8 POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA* (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: FALL AND WINTER		
<i>Allium cepa</i> , <i>A canadense</i> Onions (cultivated and wild)	Cultivated and grown on rich soils throughout USA	Cattle, horses, sheep, dogs
<i>Astrolepis sinuata cochisensis</i> Jimmy fern, Cloak fern	Dry rocky slopes and crevices, chiefly limestone areas; southwest	Sheep, goats, cattle
<i>Daubentonia punicea</i> Rattlebox, Purple sesbane	Cultivated and escaped, in waste places; southeastern USA coastal plain	All
<i>Glottidium vesicarium</i> Bladderpod, Rattlebox, Sesbane, Coffeebean	Mostly open, low ground, abandoned cultivated fields; southeastern USA coastal plain	All

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA* (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: FALL AND WINTER		
Biennials and perennials, bulb plants, onion odor. Leaves basal, green, hollow, cylindrical (<i>A cepa</i>), lustrous green, flat (<i>A canadense</i>); flowers on hollow flowering stalks, terminal umbels of many small blooms; fruits 3-celled capsules with many seeds.	N-propyl disulfide, an oxidant, in all parts. Anemia develops within days of exposure. Toxicosis in cattle associated with prolonged ingestion of large amounts of onions. N-propyl disulfide inhibits RBC glucose-6-phosphate dehydrogenase, leading to hemolysis and formation of Heinz bodies. Clinical signs are hemoglobinuria, diarrhea, loss of appetite, jaundice, ataxia, collapse, and possible death if untreated. Hemolytic anemia reported in livestock ingesting wild onions. Heinz body anemia; swollen, pale, necrotic liver; hemosiderin in liver, kidneys, and spleen are reported pathologic lesions.	Clinical signs similar to toxicity induced by S-methylcysteine sulfoxide (a rare toxic amino acid in <i>Brassica</i> spp) in livestock. Susceptibility to onion poisoning varies across animal species: cattle more susceptible than horses and dogs, which are more susceptible than sheep and goats. Remove animals from source and prevent future access to cull onions. Symptomatic and supportive care essential.
Evergreen from rhizomes, perennial, erect fern with divided leaves, folding when dry. Leaflets about as wide as long, scaly on back.	Unknown (excreted in milk). Nervous syndrome, incoordination, arched back, trembling, increased respiratory rate and pulse. Death when not allowed to rest.	No specific treatment. Supportive and general nursing care helps. Avoid driving during danger period. Provide ample watering, placed to avoid long walks. Allow rest if signs occur.
Annuals or perennials, shrub. Leaves pinnately compound with ≥ 20 leaflets. Flowers orange-red, rose, or purple. Legume pods (≥ 5 seeds) longitudinally 4-winged.	<i>S punicea</i> most toxic species (0.1% body wt toxic to sheep and cattle). Toxin(s) not fully characterized, but saponins are primary suspects; 12–24 hr delay in clinical signs after ingestion. Rapid pulse, weak respiration, diarrhea, death.	Symptomatic treatment; specific cause unknown. Seeds poisonous. Remove animal from source. Fluids and electrolytes for dehydration.
Tall annual. Legume pods flat, tapered at both ends, 2-seeded. Leaves pinnate, divided. Flowers yellow.	Unknown (green plant and seeds). In ruminants, hemorrhagic diarrhea, shallow rapid respiration, fast irregular pulse, coma, death. Lesions include hemorrhages in abomasum and intestines, dark tarry blood.	Green seeds are more toxic. Remove animal from source immediately. Symptomatic, general supportive treatment—saline purgatives, rumen stimulants, IV fluids.

(continued)

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: FALL AND WINTER (continued)		
<i>Halogeton glomeratus</i> Halogeton	Deserts, overgrazed areas, winter ranges, alkaline soils; western USA	Sheep, cattle
<i>Isocoma pluriflora</i> (<i>Haplopappus heterophyllus</i>) Rayless goldenrod, Burroweed, Jimmy-weed	Dry plains, grasslands, open woodlands, and along irrigation canals; alkaline soils; southwestern USA and northern Mexico	Cattle, sheep, horses
<i>Juglans nigra</i> Black walnut	Native to eastern USA; now from eastern seacoast, west to Michigan and most of the Midwest, south to Georgia and Texas	Horses
<i>Melilotus officinalis</i> and <i>M alba</i> Sweet clover, White sweet clover	Commonly found on alkaline soils, fields, roadsides, and waste places; forage crop in southern and northern USA	Most commonly cattle, also horses and sheep
<i>Sophora secundiflora</i> Mescal bean, Coral bean, Sophora, Frijolito, Texas mountain laurel	Hills and canyons, limestone soils; southwestern Texas into Mexico	Cattle, sheep, goats

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: FALL AND WINTER (continued)		
Annual herb. Leaves fleshy, round in cross-section, tip with stiff hair. Axillary flowers inconspicuous. Fruits bracted and conspicuous.	Oxalic acid, oxalate. Acute course. Rapid labored respiration, depression, weakness, coma, death. Lesions include hemorrhages and edema of rumen wall, swollen kidneys, oxalate crystals in kidneys and rumen wall.	Toxic dose consumed over short period. Increase water consumption. Standard therapy IV calcium borogluconate (helpful in cattle, delay deaths in sheep). Calcium supplement (83% alfalfa, 15% calcium carbonate, 2% molasses) in feed before grazing. Halogeton forage can be helpful. Herbicide 2,4-D control.
Bushy perennial 2–4 ft tall, with many yellow flowerheads. Leaves alternate, linear, sticky.	Complex benzyl alcohol (tremetol); resin acid; primarily nursing young and nonlactating animals. Reluctance to move, trembling, weakness, vomiting, dyspnea, constipation, prostration, coma, death.	"Milk sickness." Similar treatment to <i>E. rugosum</i> intoxication. Prevent access to plants (growing season). Remove young and discard milk (hazardous to people).
Tree with deciduous, alternate, pinnately compound leaves (numerous lanceolate leaflets with serrated margins); leaflets in middle are largest. Male and female flowers on same tree but different inflorescences. Thick husked nut does not open when ripe. Twigs have chambered pith.	Juglone, phenolic derivative of naphthoquinone. Shavings with as little as 20% black walnut toxic within 24 hr of exposure. Reluctance to move; depression; increased temperature, pulse, respiration rate, abdominal sounds, digital pulse, hoof temperature; distal limb edema; lameness. Severe laminitis with continued exposure.	Nonfatal; laminitis and edema of lower limbs. Remove shavings promptly (relief signs). Treat for limb edema and laminitis. Improvement in 24–48 hr with no sequelae. NSAIDs are mainstay; prazosin, nifedipine are promising. Avoid corticosteroids (worsen existing vasoconstriction).
Annual or biennial herb 3–6 ft tall. Leaves alternate, pinnately compound with 3 obovate leaflets, serrated margins. Yellow or white flowers on racemes. Small 1-seeded pods.	See SWEET CLOVER POISONING, p 3156.	See p 3156.
Evergreen shrub or small tree. Leaves alternate, divided, and leathery. Flowers violet-blue, fragrant. Seeds large and bright red with hard seed coat, in legume pod.	Quinolizidine alkaloid (seeds and probably leaves). Violent trembling, stiff gait, falling on exercise, recumbent for a few minutes, becoming alert and eating.	Symptomatic. Toxic effect not cumulative, consume large amounts quickly. Seeds more dangerous when crushed.

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
 DANGEROUS SEASON: FALL, WINTER, AND SPRING		
<i>Melia azedarach</i> Chinaberry	Fence rows, brush, waste places; southern USA	Pigs and sheep, others (dogs) less susceptible
 DANGEROUS SEASON: ALL SEASONS		
<i>Acacia berlandieri</i> Guajillo, Catclaw, Blackbrush, Acacia	Semiarid rangelands; southwest- ern Texas into Mexico	Sheep, goats
<i>Agave lechuguilla</i> Lechuguilla	Low limestone hills, dry valleys, and canyons; southwest. Dangerous all seasons, especially spring.	Sheep, goats, cat- tle, usually dur- ing drought
<i>Agrostemma githago</i> Corn cockle	Weed, grainfields, and waste areas; throughout North America	All
<i>Asclepias</i> spp Milkweeds	Dry areas, usually waste places, roadsides, streambeds, western USA	All
<i>Astragalus</i> spp, <i>Oxytropis</i> spp (certain species only) Locoweed	Mostly western	All grazing animals

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: FALL, WINTER, AND SPRING		
Small to medium deciduous tree. Fruit cream or yellow with a furrowed globose stone, persisting on tree through winter. Large amount required for intoxication.	Several alkaloids and a saponin (all parts), fruit most toxic. Restlessness, vomiting, constipation, cyanosis, rapid pulse, dyspnea, death within 24 hr.	Gastroenteritis usual. Recovery may be spontaneous. Laxatives and GI protectants suggested.
DANGEROUS SEASON: ALL SEASONS		
Deciduous shrub or small tree. Leaf divided. Flowers white to yellowish in dense heads. Fruit a legume with margins thickened.	Amine, N-methyl- β -phenylethylamine. Chronic course. Ataxia of hindquarters (limberleg), marked excitation, prostration, remain alert, death from starvation.	Dominates vegetation in some areas. Valuable to sheep industry due to high nutritive value and dominance. Supplement during drought to reduce possibility of poisoning.
Perennial, stemless, with thick, fleshy, tapered leaves having sharply serrated margins. Flowers infrequently with tall terminal panicle.	Unidentified hepatotoxin (causing photosensitivity) and a toxic saponin (abortifacient action). Subacute course. Listlessness, anorexia, icterus, yellow discharge from eyes and nostrils, photosensitization, coma, death.	Remove animals from range and provide shade. <i>See</i> PHOTOSENSITIZATION, p 976.
Green winter annual with silky-white hairs, opposite leaves, purple flowers, black seeds.	Saponin (githagenin) in seeds. Acute course. Profuse watery diarrhea, vomiting, dullness, general weakness, tachypnea, hemoglobinuria, death.	Maintain hydration (fluids and electrolytes) and control diarrhea. Oils and GI protectants. Neutralize toxin (dilute acetic acid PO). Blood transfusions may be necessary.
Perennial erect herbs, shrubs, vines, or small trees with milky sap. Leaves simple, opposite/whorled with entire margins. Seeds silky-hairy from elongated pods.	Steroid glycosides and toxic resinous substances (all parts), green or dry. Staggering, tetanic convulsions, bloating, dyspnea, dilated pupils, rapid and weak pulse, coma, death.	Sedatives, laxatives, and IV fluids suggested. Prevent plant consumption. Do not feed milkweed-contaminated hay.
Stemmed or stemless perennial herbs. Leaves alternate and pinnately compound. Flowers leguminous. Chronic intoxication.	Swainsonine. Depression, emaciation, incoordination, dry lusterless hair. Abortions. Neurovisceral cytoplasmic vacuolation, congestive right heart failure in cattle grazing at high altitudes.	Avoid grazing of source. Both green and dry plants toxic.

(continued)

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: ALL SEASONS (continued)		
<i>Astragalus</i> spp (certain species only) Milk vetch, etc (many common names)	Nearly all	All grazing animals
<i>Astragalus</i> spp (certain species only—selenium accumulators) Many common names	Seleniferous areas, mostly western and midwestern	All grazing animals
<i>Baccharis</i> spp Silverling, Baccharis, Yerba-de-pasmo	Open areas, often moist; southeastern and southwestern USA	Cattle
<i>Brassica</i> spp, <i>Raphanus</i> spp, <i>Descurainia</i> spp, <i>Berteroa incana</i> Mustards, Crucifers, Cress; and for <i>B incana</i> , Hoary alyssum, Hoary false alyssum	Fields, waste areas, hay meadows, roadsides; throughout North America	Cattle, horses, pigs
<i>Cestrum diurnum</i> , <i>C nocturnum</i> Day-blooming jessamine and night-blooming jessamine, respectively	Open woods and fields; Gulf Coast states (Florida, Texas) and California	Cattle, horses, and dogs (ingesting cholecalciferol-based rodenticides)

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: ALL SEASONS (continued)		
As above.	Miserotoxin, other aliphatic nitro compounds. Posterior paralysis, goose-stepping, depression, rough coat, pulmonary emphysema, acute death, cord demyelination.	Avoid grazing of preflower stage.
As above.	Selenium (chronic). Slow growth, reproductive failure, loss of hair, sore feet, acute death.	Avoid grazing seleniferous plants for extended periods. See SELENIUM TOXICOSIS, p 3085.
Shrubs. Numerous small, whitish flowers. Leaves resin-dotted and persistent southward.	Unidentified. Acute course. Rumen stasis, bloat, anorexia, excess salivation, diarrhea, staggering, trembling, restlessness, polypnea, tachycardia, death.	Most dangerous in early growing stage. Toxin concentrated in leaves and flowers. No specific treatment. Treatment toward relief of diarrhea is best.
Annuals/biennials herbaceous weeds with terminal clusters of yellowish flowers and slender, elongated seed pods.	Glucosinolates (isothiocyanate, thiocyanates, nitrites) in seeds and vegetative parts, fresh or dry. Acute/chronic course. Anorexia, severe gastroenteritis, salivation, diarrhea, paralysis, photosensitization, hemoglobinuria. Unknown toxin(s) in <i>B. incana</i> cause rapid onset of transient distal limb edema, laminitis (horses), and severe GI disturbances with continued exposure. Late abortions and/or weak, premature foals at birth.	No specific treatment (<i>B. incana</i> disease in horses). Phenylbutazone, flunixin, furosemide or other diuretics helpful in relieving pain, inflammation, and edema. Remove from source. Administer GI protectants (mineral oil).
Evergreen shrubs or tall bush; leaves alternate, ovate smooth-edged; flowers white, tubular, small clusters, fragrant by day; fruit, a greenish-white to lavender (immature), becoming dark purple to black (mature), fleshy berry, with several small, black, oblong seeds, dispersed by birds in droppings. Leaves longer, night fragrant flowers, white fruits at maturity (<i>C. nocturnum</i>).	Atropine-like alkaloids (fruit), saponins (fruit and sap), and glycosides of 1,25-dihydroxycholecalciferol (leaves primarily, stem, fruits, and roots) are found. Gastroenteritis develops on ingestion of fruits. Vomiting, depression, anorexia, chronic weight loss with normal appetite, choppy stiff gait, increased pulse, persistent hypercalcemia and hyperphosphatemia, calcinosis (aorta, carotid and pulmonary arteries, tendons, ligaments, and kidneys). Parathyroid atrophy, thyroid (C-cell) hypertrophy, and osteopetrosis reported with chronic ingestion of leaves.	Prevent further access of animals to plants. In early stages, treatment might be effective and cost-effective. Correct fluid and electrolyte imbalances in cases with persistent vomiting or diarrhea. Reduce or prevent hypercalcemia (calciuresis, diuretics, steroids, calcitonin). Maintenance therapy of diuretics and steroids may be necessary.

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: ALL SEASONS (continued)		
<i>Conium maculatum</i> Poison hemlock	Roadside ditches, damp waste areas; throughout North America	All
<i>Crotalaria</i> spp Crotalaria, Rattlebox	Fields and roadsides; eastern and central USA	All
<i>Cynoglossum officinale</i> Hound's tongue	Common in waste places, roadsides, and pastured areas throughout USA	Cattle, sheep, horses
<i>Datura stramonium</i> Jimson weed, Thorn apple	Fields, barn lots, trampled pastures, and waste places on rich bottom soils; throughout North America	All

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: ALL SEASONS (continued)		
Purple-spotted hollow stem. Leaves resemble parsley, parsnip odor when crushed. Taproot. Flowers white, in umbels.	Piperidine alkaloids (coniine and others) in vegetative parts. Acute course. Dilated pupils; weakness; staggering gait; slow pulse, progressing to rapid and thready. Slow, irregular breathing; death from respiratory failure. Teratogenic in cattle.	Coniine excreted via lungs and kidneys, mousy odor of breath and urine diagnostic. Administer saline cathartics; neutralize alkaloids with tannic acid, together with stimulants.
Annual or perennial legume. Yellow flowers in racemes, pods inflated. Bracts at base of pedicels of flowers and fruits persistent. Leaves simple or divided. Seeds in harvested grain.	Pyrrolizidine alkaloid (monocrotaline) and other unidentified alkaloids (all parts, especially seeds). Chronic course. Chickens—diarrhea, pale comb, ruffled feathers; horses—unthriftness, ataxic, walking in circles, icterus; cattle—bloody diarrhea, icterus, rough coat, edema, weakness. Death may occur from a few weeks to months after ingestion.	Cumulative, fresh or dry. No treatment.
Annual or biennial herbaceous plant, rough hairy stem and foliage, 3–4 ft tall. Leaves alternate, oblanceolate, narrowed to petiole (lower), lanceolate, sessile, clasping (upper). Flowers numerous in coiled racemes, without bracts, blue, purple, or white blooms. Fruit, burr-like from 4 nutlets, thickly covered with hooked prickles.	Pyrrolizidine alkaloids (0.6%–2.1% of dry matter) including heliosupine and echinatine in the foliage. Unpleasant odor discourages consumption when fresh, becomes palatable in hay and is readily consumed. Toxic insult primarily hepatic and chronic in nature. Pyrrolizidine alkaloids (inactive) undergo hepatic metabolism to active intermediates—pyrroles (alkylating agent), which are toxic. Clinical signs are anorexia, depression, rough hair coat, hemorrhage, tenesmus, bloody feces, ataxia, jaundice, death. Hepatic lesions of necrosis, edema, megalocytosis, bile duct hyperplasia, and cytoplasmic vacuolation reported.	Know source and quality of hay. Treatment symptomatic and supportive at best. Affected animals seldom recover.
Leaves wavy. Flower large (4 in.), white, tubular. Fruit a spiny pod, 2 in. (5 cm) long.	Tropane alkaloids (atropine, scopolamine, hyoscyamine) in all parts, seeds in particular. Acute course. Weak rapid pulse and heartbeat, dilated pupils, dry mouth, incoordination, convulsions, coma.	All parts, mainly in hay or silage. Urine from animal dilates pupils of laboratory animals (diagnostic). Treatment nonspecific; cardiac and respiratory stimulants (physostigmine, pilocarpine, arecoline).

(continued)

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
 DANGEROUS SEASON: ALL SEASONS (continued)		
<i>Drymaria pachyphylla</i> Inkweed, Thickleaf drymary	Heavy alkaline clay soil in low areas or dry, overgrazed pastures; southwestern USA	Cattle, sheep, goats
<i>Festuca arundinacea</i> Tall fescue	A coarse, hardy, drought-resistant grass; Pacific Northwest, Missouri, Oklahoma, and Kentucky; major pasture grass in southeastern USA	Mostly cattle and horses
<i>Gelsemium semper-virens</i> , <i>G. rankinii</i> Yellow jessamine, Evening trumpet flower, Carolina jessamine	Open woods, thickets, swamps, low areas, and open fields; southeastern USA	All
<i>Gutierrezia microcephala</i> Threadleaf, Snake- weed, Small-head matchweed, Sticky snakeweed	Widespread over dry range and desert; primarily southwestern USA	Cattle, sheep, goats, pigs
<i>Helenium hoopesii</i> Orange sneezeweed	Moist slopes and well-drained mountain meadows; abundant in overgrazed areas; western USA	Sheep, rarely cattle
<i>Helenium microcephalum</i> Small head sneezeweed	Moist ground; southern USA	Cattle, sheep, goats

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: ALL SEASONS (continued)		
Multibranched, succulent, prostrate annual. Opposite or whorled appearing leaves. Small white flowers.	Problem in heavily overgrazed areas. Unknown toxin. Sudden onset of diarrhea, restlessness, depression, coma, death. Lesions include gastroenteritis with congestion of liver, kidneys, spleen. Petechial hemorrhages on heart.	Dangerous during drought, after rain, or at night. Avoid overstocking to improve range. In well-fed and watered animals, little or no problem observed. Poor response to treatment.
Coarse, deeply rooted perennial grass. Broad, dark-green, ribbed, rough upper surface, and smooth sheathed leaves. Grows in clumps.	See FESCUE POISONING, p 3016.	See p 3016.
Climbing or trailing vines. Evergreen, entire, opposite leaves. Yellow tubular flowers, very fragrant.	Potent neurotoxic alkaloids (gelsemine and others, related to strychnine) in all parts. Gelsemine the most toxic. Acute course. Weakness, incoordination, dilated pupils, convulsions, coma, death within 48 hr. Limberneck in fowl. Clinical signs indicative of a poor prognosis.	No specific treatment. Relaxants and sedatives suggested. PO administration of strong tea/coffee or poison hemlock suggested on early exposure (before observation of clinical signs) seems helpful in reducing further toxin absorption (more basic stomach pH).
Multibranched, perennial (toxicologically significant), resinous shrub. Simple leaves, alternate; yellow-flowered heads.	Unknown. Steroidal effect of saponins, mono- and diterpene acids. Acute poisoning, anorexia, listlessness, hematuria, diarrhea followed by constipation. In cattle, abortions with retained placenta, stillbirths, or premature and weak calves.	No specific treatment. Supplementing diet will help but not entirely prevent abortion in cattle.
Annuals, biennials, perennial herb. Orange sunflower-like heads or yellow flowers. Leaves alternate.	Sesquiterpene lactones (helenalin, hymenoxin). Subacute course (spewing sickness). Depression, weakness, restlessness, stiff gait, salivation, pronounced vomiting, emaciation, eventual death.	Cumulative. Aspiration pneumonia frequent. Remove from access to plant. Graze sneezeweed areas for only short periods of time. Can graze intermittently with some success.
Annual, erect herb, simple-stemmed below, bushy above. Stem winged. Narrow leaves throughout. Flowers in small heads; disk pale red-brown, rays yellow.	Sesquiterpene lactone (helenalin) in flowering stage. Depression, weakness, restlessness, stiff gait, salivation, vomiting.	Cumulative. Remove from pasture. Cathartics may help.

TABLE 8 POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: ALL SEASONS (continued)		
<i>Hypericum perforatum</i> St. John's-wort, Goatweed, Klamath weed	Dry soil, roadsides, pastures, ranges; throughout North America	Sheep, cattle, horses, goats
<i>Kalmia</i> spp Laurel, Ivybush, Lambkill	Rich moist woods, meadows, or acid bogs; eastern and northwestern. Dangerous all seasons, especially winter and spring.	All, often sheep
<i>Kochia scoparia</i> Kochia, Burning bush, Fireball, Fireweed, Poor man's alfalfa	Throughout North America	Cattle, sheep
<i>Ligustrum</i> spp Privet, Ligustrum, Hedge plant	An ornamental; common as hedge; found at abandoned farm home sites, along fences, and in bottomlands; eastern USA	All livestock
<i>Lupinus</i> spp Lupines, Silky lupine, Sink lupine, Bluebonnet	Dry to moist soils, roadsides, fields, and mountains; throughout, but poisoning mostly western USA	Sheep, cattle, goats, horses, pigs

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA* (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: ALL SEASONS (continued)		
Perennial herb or woody below. Leaves simple, opposite or whorled, dotted. Flowers many, yellow, with many stamens.	Photodynamic pigment (hypericin). Subacute course. Photosensitization, pruritus and erythema, blindness, convulsions, diarrhea, hypersensitivity to cold water contact, death.	Remove animals from source and sunlight. Corticosteroids parenterally, topical broad-spectrum antibiotics.
Woody shrub. Evergreen, glossy leaves. Flowers pink to rose, showy.	Resinoid (andromedotoxin) and a glucoside (arbutin) in vegetative parts. Acute course. Incoordination, excess salivation, vomiting, bloat, weakness, muscular spasms, coma, death.	Undigested rumen contents and ingesta in lungs at necropsy. Laxatives, demulcents, nerve stimulants, atropine.
Annual to 5 ft tall. Many branched stems give bushy appearance. Leaves petiolate, lanceolate, thin, and flat; alternate. Fruit has 5 wedge-shaped wings.	An alkaloid has been suggested. This plant may also accumulate nitrate and oxalate. Disease syndromes: photosensitization, weight loss, and polioencephalomalacia, which seems intensified by slow growth and sulfates.	Harvested foliage is source of toxin. Protect from sun in case of photosensitization; treat polioencephalomalacia with vitamin B. Supplement with copper (preventive against polioencephalomalacia).
Shrubs up to 15 ft tall. Simple, opposite, short-petioled, evergreen or deciduous leaves. Numerous small, white flowers in panicles. Fruit is 1- to 2-seeded, black or dark blue berry that persists throughout winter.	Ligustrin, ligustron, syringin, syringopicrin, and other unknown compounds in leaves and fruit. Primarily GI irritants. Diarrhea, abdominal pain, incoordination, paresis, weak pulse, hypothermia, convulsions, sometimes death.	Treatment symptomatic and supportive; correct dehydration.
Perennials. Leaves simple or palmately divided. Flowers blue, white, red, or yellow in terminal raceme.	Quinolizidine alkaloids (20 known) concentrated in seeds (fresh and dry); some piperidine alkaloids. Acute course. Inappetence, dyspnea, struggle, convulsions, death from respiratory paralysis. Lupinosis (hepatotoxicosis) not a reported problem in the USA. Some species teratogenic in cattle (crooked calf disease, weak and deformed calves, stillbirths).	Do not disturb sick animals; remove from source as they begin to recover. No effective treatment, but survivors recover completely. <i>See also</i> p 3018.

(continued)

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA* (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: ALL SEASONS (continued)		
<i>Nandina domestica</i> Nandina, Heavenly bamboo, Chinese sacred bamboo	Common ornamental in southern USA	All grazing animals, especially ruminants
<i>Nerium oleander</i> Oleander, Laurel rosa, Laurel blanco	Common ornamental in southern regions	All
<i>Photinia fraseri</i> , <i>P serrulata</i> , <i>P glabra</i> Fraser's photinia, Chinese photinia, Red leaf photinia, Red tip photinia	Common ornamental (hedge or screen) in southern USA	All grazing animals, mostly ruminants
<i>Pinus ponderosa</i> Ponderosa pine, Western yellow pine	Coniferous forests of Rocky Mountains at moderate elevations; western USA. Dangerous all seasons, especially winter.	Cattle. Sheep and deer seem not to be affected.
<i>Prunus caroliniana</i> Laurel cherry, Cherry laurel, Mock orange	Woods, fence rows, and often escaped from cultivation; southern regions. Dangerous all seasons, especially winter and spring.	All grazing animals

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: ALL SEASONS (continued)		
Upright, unbranched, and multistemmed, evergreen shrub, 3–7 ft tall. Alternate, bi- to tripinnately compound leaves; leaflets subsessile, elliptic-lanceolate, half as wide as long, entire, leathery, metallic bluish-green becoming purple in fall. Small, white flowers; 2-seeded, bright red berries in large panicles persist throughout fall and winter.	Cyanogenic glycosides in foliage and fruits, hydrolyzed in GI tract to free cyanide, thereby affecting cellular respiration. See CYANIDE POISONING, p 2959. Prognosis good if animal survives for 1 hr after signs begin.	Acute outcome precludes effective treatment for most; IV sodium nitrite/sodium thiosulfate treatment of choice. Picrate test indicates toxic potential of the plant. See CYANIDE POISONING, p 2959.
Evergreen shrub or tree. Leaves whorled and prominently, finely, pinnately veined beneath. Flowers showy, white to deep pink.	Digitoxin-type glycosides (oleandroside, nerioside, and others) in all parts, fresh or dry. Acute course. Severe gastroenteritis, vomiting, diarrhea, increased pulse rate, weakness, death.	No specific treatment. Atropine in conjunction with propranolol reported helpful.
Evergreen shrubs, 10–15 ft tall. Alternate, oblong-ovate serrated leaves, copper-red (when young) turning dark green in 2–4 wk. Prominent, whitish flowers in spring; showy, red berries in fall.	Same as for <i>N domestica</i> (above).	Same as for <i>N domestica</i> .
Evergreen tree, 150–180 ft. Leaves in groups of 3, yellowish green, 7–11 in. long. Small soft cones, seeds mature in 2–3 yr. Bark platy, reddish orange.	Unknown toxin (diterpene esters of isocupressic acid are suspected). Chronic course. Abortions in late gestation, stillbirths or weak calves, depressed, edema of vulva and udder, retained placenta.	Pine-needle ingestion during last half of gestation—may abort after single exposure. Supportive care, remove retained placenta, treat metritis, provide good nutrition. Keep pregnant cows away from source.
Leaves evergreen, shiny, leathery. Broken twigs with strong cherry bark odor. Fruit black.	Hydrocyanic acid (wilted leaves, bark, and twigs). Peracute course. Difficult breathing, bloat, staggering, convulsions, followed by prostration and death. Mucous membranes and blood bright red.	See CYANIDE POISONING, p 2959.

(continued)

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA* (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: ALL SEASONS (continued)		
<i>Prunus</i> spp Chokecherries, Wild cherries, Peaches	Waste areas, fence rows, woods, orchards, prairies, dry slopes	All grazing animals, mostly cattle and sheep
<i>Psilostrophe</i> spp Paperflowers	Open range lands and pastures; southwestern USA	Sheep primarily; cattle and goats less susceptible and less likely to eat the plant.
<i>Pteridium aquilinum</i> Bracken fern, Bracken, Brake fern	Dry poor soil, open woods, sandy ridges, throughout North America	All grazing animals
<i>Ricinus communis</i> Castor bean	Cultivated in southern regions	All
<i>Senecio</i> spp Groundsel, Senecio	Grassland areas; mostly western USA	Cattle, horses, sheep to a limited extent in USA
<i>Sorghum halepense</i> Johnson grass	Weed of open fields and waste places; southern and scattered north to New York and Iowa	All grazing animals
<i>Sorghum vulgare</i> Sorghum, Sudan grass, Kafir, Durra, Milo, Broomcorn, Schrock, etc	Forage crops and escapes; throughout North America	All

TABLE 8

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: ALL SEASONS (continued)		
Large shrubs or trees. Flowers white or pink. Cherries or peaches. Crushed twigs with strong odor.	Glycoside-yielding cyanide (rumen hydrolysis). Excitement leading to depression, dyspnea, incoordination, convulsions, prostration. Death may occur in 15 min from asphyxiation.	Mucous membranes, bright pink color; blood, bright red color. See CYANIDE POISONING, p 2959.
Perennial composite. Erect, woolly stems branching from base. Leaves simple, alternate, petioled. Many small heads of yellow flowers.	Sesquiterpene lactone. Depression, incoordination, anorexia, weakness, trembling, rapid irregular pulse and respiration, coughing, vomiting, aspiration pneumonia, death.	Antimicrobial actions of sesquiterpene lactone in rumen affect metabolism. Supplement diet with sodium sulfate and high protein.
Leaves firm, leathery, 3-pinnate.	See BRACKEN FERN POISONING, p 3089.	See p 3089.
Large, palmately lobed leaves. Seeds resembling engorged ticks, usually 3 in somewhat spiny pod.	Phytotoxin—ricin in all parts (seeds especially toxic). Acute to chronic course (death or recovery). Violent purgation, straining with bloody diarrhea, weakness, salivation, trembling, incoordination.	Diagnosis based on presence of seeds, RBC agglutination, precipitin test. Specific antiserum, ideal antidote; sedatives, arecoline hydrobromide, followed by saline cathartics suggested.
Perennial or annual herbs. Heads of yellow flowers with whorl of bracts below.	Pyrolizidine alkaloids, volatile oils, and nitrogen oxides (fresh or dry). Acute poisoning not common. Dullness, aimless walking, increased pulse, rapid respiration, weakness, colic, delayed death (days to months). In cattle, prolapsed rectum from persistent straining. In horses, nervous signs evident in later stages.	Effects are cumulative. Liver biopsy diagnostic in early stages. Liver function test of value for subclinical condition in cattle. No general treatment. See also p 3150.
Coarse grass with large rhizomes and white midvein on leaf. Topped by large, open panicle.	Same as for <i>S vulgaris</i> (below).	Same as for <i>S vulgaris</i> .
Coarse grasses with terminal flower cluster. Some to 8 ft tall.	Hydrocyanic acid (drought, trampling, frost, second growth) and nitrate (heavy in vegetative parts). Acute course. Difficult breathing, bloat, staggering, convulsions, death. Blood bright red (cyanide) or chocolate brown (nitrate).	Hay safe for cyanide (volatile), not safe for nitrate (analyze). See CYANIDE POISONING, p 2959, and NITRATE AND NITRITE POISONING, p 3049.

POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Scientific and Common Names	Habitat and Distribution	Affected Animals
DANGEROUS SEASON: ALL SEASONS (continued)		
<i>Taxus</i> spp Yew	Most of North America; Japanese and English yew common ornamentals	All except deer
<i>Triglochin</i> spp Arrowgrass	Salt marshes, wet alkaline soils, lake shores; dangerous all seasons, especially dry season; northern half of North America	Sheep, cattle

^a Images for many of the plants described here, as well as for plants of Australia, the Caribbean, and South Africa, are available online at www.merckvetmanual.com.

PYRROLIZIDINE ALKALOIDOSIS

(Seneciosis, *Senecio* poisoning, Ragwort toxicity)

Typically, pyrrolizidine alkaloidosis is a chronic poisoning that results in hepatic failure. It is caused by many toxic plants, most commonly of the genera *Senecio*, *Crotalaria*, *Heliotropium*, *Amsinckia*, *Echium*, *Cynoglossum*, and *Trichodesma*. These plants grow mainly in temperate climates, but some (eg, *Crotalaria* spp) require tropical or subtropical climates. The plants most often implicated include ragwort (*S. jacobea*), groundsel (*S. riddellii*, *S. longilobus*), rattleweed (*Crotalaria retusa*), and seeds of yellow tarweed (*A. intermedia*).

Cattle, horses, farmed deer, and pigs are most susceptible; sheep and goats require ~20 times more plant material than cattle. Individual susceptibility varies greatly within species; young growing animals are most susceptible.

Etiology and Pathogenesis: More than 300 toxic factors (alkaloids with a pyrrolizidine base) have been found in plants, with some plants containing a mixture of several different pyrrolizidine alkaloid toxins. *S. jacobea* contains jacobine; retrorsine, seneciphylline, and monocrotaline are other pyrrolizidine alkaloids frequently incriminated in toxicities.

These plants, which under normal conditions are avoided by grazing animals, may be eaten during drought conditions. Some animals may eat these plants preferentially as roughage when they are available on extremely lush pasture. Animals are also poisoned by eating the plant material in hay, silage, or pellets. Seeds from *Crotalaria*, *Amsinckia*, and *Heliotropium* spp, which have been harvested with grain, have caused disease in horses, cattle, pigs, and poultry.

TABLE 8 POISONOUS RANGE PLANTS OF TEMPERATE NORTH AMERICA^a (continued)

Important Characteristics	Toxic Principle and Effects	Comments and Treatment
DANGEROUS SEASON: ALL SEASONS (continued)		
Evergreen perennial tree or shrub. Bark reddish brown then flaking in scales. Leaves linear, 0.5–1 in. (1.5–2.5 cm) long, 2-ranked on twig, upper surface dark green, lower yellow-green, midribs prominent. Flowers unisexual, inconspicuous. Fruit single stony seed. Bright scarlet color.	Toxic alkaloids in bark, leaves, seeds. Gaseous distress, diarrhea, vomiting, tremors, dyspnea, dilated pupils, respiratory difficulty, weakness, fatigue, collapse, coma, convulsions, bradycardia, circulatory failure, death. Death may be rapid.	Poisoning usually results when branches and trimmings fed to livestock.
Grasslike, except leaves are thick. Heads of fruits globular on erect raceme. Flowers inconspicuous.	Hydrocyanic acid in leaves. Salivation, dyspnea, excitement followed by depression, incoordination, prostration, convulsions followed by death from anoxia.	Often, animals found dead. <i>See</i> CYANIDE POISONING, p 2959.

The alkaloids are metabolized in the liver to highly reactive pyrroles, which produce cytotoxic effects on target sites, most commonly the nuclei of hepatocytes. Other target sites may include the epithelial and vascular tissues of the kidneys and lungs. These toxic pyrroles cross-link DNA strands and also unite DNA with nucleoproteins such as actin. These molecular alterations are presumed to create the cytotoxic, antimutagenic, and megalocytic effects characteristic of pyrrolizidine alkalosis.

Clinical Findings: Hepatic pathology with associated clinical signs is the most common manifestation of pyrrolizidine alkalosis in domestic animal species. Acute intoxication is characterized by sudden death from hemorrhagic hepatic necrosis and visceral hemorrhages. This is a rare event, because the poor palatability of these plants makes rapid ingestion of large quantities of the toxins uncommon. More chronic exposure is typical, and the liver reflects the cumulative and progressive effects of repeated ingestion of small doses of toxin. Clinical signs may not be seen for several weeks or months after initial exposure. Consumption of the offending

plant may even have ceased months earlier. The ongoing hepatic damage in these instances is suspected to be due to the recycling of toxic pyrroles as they are released from one dying cell and taken up by another. Clinical progression may also be altered by concurrent hepatic pathology; a hemolytic crisis may be precipitated in sheep with excessive hepatic copper stores (*see* p 3073).

In horses and cattle, signs include loss of condition, anorexia, dullness, and constipation or diarrhea. Tenesmus and passing of bloodstained feces may be followed by rectal prolapse, especially in cattle. Ascites and icterus may be present, and cattle and sheep sometimes show intermittent photosensitization (*see* p 976). Some animals become progressively weaker and reluctant to move. Others exhibit signs of hepatic encephalopathy such as head-pressing, yawning, aimless wandering, or even frenzied and aggressive behavior. Pica may be seen. Death may occur suddenly or after prolonged recumbency with hepatic coma and high levels of ammonia in the blood.

Less common clinical signs that have been described with pyrrolizidine toxicoses include inspiratory dyspnea in ponies due to laryngeal and pharyngeal paralysis, dyspnea

due to interstitial pneumonia in horses, and renal disease in pigs.

Lesions: In acute cases, the liver may be enlarged, hemorrhagic, and icteric. In chronic cases, it is atrophied, fibrous, finely nodular, and usually pale with a glistening surface due to fibrous thickening of the capsule. Other livers are markedly icteric. The gallbladder is often edematous and grossly distended with thick, mucoid bile. Edema of the abomasum and segments of the bowel, mesentery, and associated lymph nodes is common, and there may be ascites. In some cases, numerous small hemorrhages are present in the abdominal serous membranes. The lungs of some severely affected horses may be emphysematous and fail to collapse (often due to ingestion of *Crotalaria* spp).

Characteristic histologic changes occur in the liver. Irreversible enlargement of individual hepatocytes (megalocytosis) is often seen; it is conspicuous in horses and sheep but less pronounced in cattle. In cattle, marked perivenous fibrosis of sublobular veins is usually present, but this is not a consistent finding in horses and sheep. In all species, increases in connective tissue, both within and around the lobules, are marked. Bile duct hyperplasia is variable but may be the most striking microscopic change seen in some livers. Pulmonary changes seen in horses exposed to some *Crotalaria* spp may include hyperplasia of bronchoalveolar epithelium, congestion, septal fibrosis, and emphysema. Renal tubular lining cells and glomerular epithelial cells also may be individually enlarged in pigs.

Diagnosis: Chemical analysis of whole blood for toxic metabolites can confirm recent exposure but depends on the half-life of RBCs to which these pyrroles are bound. An ELISA that recognizes riddelliine and closely related pyrrolizidine alkaloids present in whole blood has also

been described but is not widely available. More commonly, a presumptive diagnosis is made based on clinical signs, compatible changes in biochemical parameters, and a history of exposure. When hepatic cirrhosis is extensive, hypoalbuminemia and hyperglobulinemia develop. Serum levels of fibrinogen, bilirubin, γ -glutamyl-transferase, and glutamate dehydrogenase may be increased, but it should be recognized that the insidious nature of this disease can result in surprisingly mild serum biochemical changes. Hepatic biopsy is often useful, especially if megalocytic change is seen. Other hepatotoxins, such as copper or aflatoxin, as well as infections such as chronic fascioliasis, must be considered before making the diagnosis. At necropsy the diagnosis can often be made based on gross findings, together with characteristic histologic changes in hepatic, pulmonary, and/or renal tissues. Hepatic assay for pyrrolic metabolites can also be performed.

Treatment and Control: Further intake of toxic plant material must be prevented. Animals showing signs rarely recover, and lesions present in asymptomatic animals may progress and result in further losses over several months. Because high protein intake may precipitate clinical signs, rations high in carbohydrates are indicated. Supportive treatment for dehydration and photosensitization may be needed.

Preventing further outbreaks by reducing exposure should be stressed.

Sheep are commonly used for grazing control of these plants, but this practice carries risks unless sheep destined for early slaughter are used. Biologic control of plants with predator moths, flea beetles, and seed flies has met with variable success. *Senecio* and related toxic species in pastures have been controlled satisfactorily by annual herbicide applications, preferably in spring before hay or silage conservation.

QUERCUS POISONING

(Oak bud poisoning, Acorn poisoning)

Most animals are susceptible to *Quercus* poisoning, although cattle and sheep are affected most often. Most species of oak (*Quercus* spp) found in Europe and North America are considered toxic. Clinical signs

occur 3–7 days after consumption of large quantities of young oak leaves in the spring or green acorns in the fall. Fallen trees associated with a recent storm are often reported with outbreaks. Feed restriction

before exposure plays a crucial role enhancing susceptibility. Mortality as high as 70% may be seen. Malformed calves and abortions have been reported in dams consuming acorns during the second trimester of pregnancy. The toxic principle, which appears to be pyrogallol, gallotannins, polyhydroxyphenolic compounds, or their metabolites produced by microbial hydrolysis in the rumen, binds and precipitates proteins, which results in GI and renal dysfunction.

Signs include anorexia, depression, emaciation, brisket edema, dehydration, rumen stasis, tenesmus, smell of ammonium on the breath, serous ocular or nasal discharge, polydipsia, polyuria, hematuria, icterus, and constipation followed by mucoid to hemorrhagic diarrhea. Renal insufficiency, which is evident 4–6 days after exposure, may be characterized by increased BUN and creatinine, proteinuria, glucosuria, hyperbilirubinuria, hyperphosphatemia, hypocalcemia, and urine with a low specific gravity. Pale swollen kidneys characterized by coagulative necrosis of the proximal convoluted tubular cells, perirenal edema, subcutaneous edema, ascites, and hydrothorax are common necropsy findings. Edema and subserosal petechial or ecchymotic hemorrhage of intestinal mucosa and ulceration of the esophagus and rumen may be seen. Evidence

of hepatotoxicity characterized by increased liver enzymes may also be present.

■ **Diagnosis** is based on clinical findings, necropsy, history, and histopathologic examination of the kidney (ie, nephrosis). Other common diseases that resemble oak poisoning include pigweed (*Amaranthus* spp) poisoning, aminoglycoside antibiotic poisoning, oxalate poisoning, and ochratoxicosis.

Consumption of a pelleted ration supplement (1 kg/head/day) containing 10%–15% calcium hydroxide plus access to more palatable feeds may be used as a preventive measure if exposure to acorns or oak leaves cannot be avoided. Calcium hydroxide, activated charcoal, rumenotics, and purgatives (such as mineral oil [1 L/500 kg], sodium sulfate [1 kg/400 kg], or magnesium sulfate [450 g/400 kg]) may be effective antidotes if administered early in the course of disease. Polyethylene glycol (1 g/kg/day) administered in the feed or water will bind tannins and reduce tissue damage. Fluid therapy to correct dehydration and acidosis and transplantation of ruminal microflora may be beneficial. Clinical recovery usually occurs within 60 days but is rare if renal dysfunction is severe. Improved range management to limit grazing in immature oak stands will prevent development of the syndrome.

RYEGRASS TOXICITY

ANNUAL RYEGRASS STAGGERS

This often fatal neurotoxic disease occurs in livestock of any age that graze pastures in which annual ryegrass (*Lolium rigidum*) is present and in the seedhead stage of growth. It is seen in western and southern Australia and in South Africa from November to March. Hay of *Festuca rubra commutata* (Chewing's fescue) with *Rathayibacter toxicus*-infected seedhead galls has caused a similar disease in cattle and horses in Oregon. Outbreaks of ergot alkaloid toxicity in cattle on *L. rigidum* have been reported in South Africa and should not be confused with annual ryegrass staggers.

In Australia, the responsible corynetoxins (members of the tunicaminyuracil group) are produced in seedhead galls induced by the nematode *Anguina funesta* and

colonized by *R. toxicus*. These bacteria-infected galls are present in infected annual ryegrass pastures from early spring onward, but they are most toxic when the plants senesce. Hence, animals show no sign of toxicity until late spring and summer. Spread of bacteria-infested nematodes to adjacent healthy annual ryegrass pastures is slow.

The corynetoxins are highly toxic glycolipids that inhibit specific glycosylation enzymes and therefore deplete or reduce activity of essential glycoproteins. Experimentally, the corynetoxins deplete fibronectins and cause failure of the hepatic reticuloendothelial system. Cardiovascular function and vascular integrity are consequently impaired, and peripheral circulation and oxygen distribution is compromised. Tunicamycin irreversibly downregulates the expression of specific γ -aminobutyric acid

receptors and causes cell death in cultured brain neurons. Hence, the clinical expression of the disorder is nervous.

● Outbreaks occur 2–6 days after animals graze a pasture that contains annual ryegrass infected at a toxic level. Deaths occur within hours, or as long as 1 wk after onset of signs. Characteristic neurologic signs are similar to those of perennial ryegrass staggers (see p 3154). However, mortality from annual ryegrass toxicity is commonly 40%–50% and occasionally higher. The lesions include congestion, edema, hemorrhage of the brain and lungs, and degeneration of the liver and kidneys.

Diagnosis is based on the characteristic neurologic signs of tremors, incoordination, rigidity, and collapse when stressed, with animals often becoming apparently normal again when left undisturbed. When animals are severely affected, nervous spasms supervene, and convulsions could be precipitated by either forced exercise or high ambient temperatures. A thorough history and evaluation of the pastures will assist in differentiation of staggers caused by other grasses such as perennial ryegrass, phalaris, and the ergots of paspalum and other grasses. Polioencephalomalacia and enterotoxemia are other differential diagnoses.

Clinical signs identical to those of annual ryegrass toxicity have been described in Australia in animals grazing *Agrostis avenacea* (annual blown grass), *Polypogon monspeliensis* (annual beard grass), or *Ehrharta longiflora* (annual veldtgrass) infected with nematode galls containing *R. toxicus*. These diseases have been called flood plain staggers, Stewart range syndrome, and veldtgrass staggers, respectively. Although the same bacterium is responsible for all the diseases, the *Anguina* nematode vectors of *R. toxicus* for these three grasses are different species than the *A. funesta* associated with annual ryegrass toxicity. Whereas the inflorescences of annual ryegrass infected with *A. funesta* usually appear normal, nematode-infested inflorescences of these other grasses show distinctive signs.

A significant increase in survival of sheep experimentally poisoned with tunicamycin was observed after treatment with derivatives of β -cyclodextrin. The promising result with this toxin-binding agent offers hope for treatment of animals once they have become affected with annual ryegrass staggers. Losses from the disorder can be minimized by early recognition of signs and removal to safe grazing or by reducing grazing pressure. Gall identification is difficult in annual ryegrass pastures, and in

south Australia the bacterium in emerging seedheads is detected and quantified by ELISA. Early detection of toxic fields enables farmers to mow the heads off grass or to allow grazing before the grass becomes too toxic. Grazing of hay aftermath from toxic pastures should be avoided. Burning annual ryegrass pastures in the fall destroys most of the galls colonized by bacteria and minimizes the risk of toxicity in the following season.

PERENNIAL RYEGRASS STAGGERS

This neurotoxic condition of grazing livestock of all ages occurs only in late spring, summer, and fall and only in pastures in which perennial ryegrass (*Lolium perenne*) or hybrid ryegrass are the major components. Sheep, cattle, horses, farmed deer, and llamas are susceptible. In New Zealand, a high incidence most years causes considerable loss and seriously disrupts management procedures and stock movement. Perennial ryegrass staggers occurs sporadically in parts of North and South America, Europe, and Australia.

The tremorgenic neurotoxins responsible are lolitrems, mainly lolitrem B. These indole diterpene alkaloids are produced in perennial and hybrid ryegrasses infected with the endophytic fungus *Neotyphodium lolii*. The amounts of fungal hyphae and lolitrem B in infected plants increase to toxic levels as the temperature rises in late spring and decrease again to safe levels in the cooler seasons. Mycelia of the fungus are present in all above-ground parts of infected plants but are especially concentrated in leaf sheaths, flower stalks, and seed. Infected plants exhibit no signs, and the fungus is spread only through infected seed. Viability of the endophyte gradually declines when infected seed is stored at ambient temperatures and moderate to high humidity, so that few seeds contain viable endophyte after 2 yr. Lolitrem B acts as a potent large conductance calcium-activated potassium (BK) channel inhibitor. It is thought that the incoordination observed when animals are exposed to lolitrem B is caused by interference with neuronal transmission in the cerebellum; no specific histologic lesion is recognized. *N. lolii* also produces the ergopeptine alkaloid ergovaline, which is the alkaloid responsible for fescue toxicosis. Ergovaline raises the temperature of animals in the warmer months of the year, inducing heat stress. It also depresses prolactin levels, and reduced milk yield in cows has been recorded in New Zealand and Australia.

Signs develop gradually over a few days. Fine tremors of the head and nodding movements are the first signs noted in animals approached quietly and watched carefully. Noise, sudden exercise, or fright elicits more severe signs of head nodding with jerky movements and incoordination when first moved. Running movements are stiff and bounding with marked incoordination and often result in collapse in lateral recumbency with opisthotonos, nystagmus, and flailing of stiffly extended limbs. In less severe cases, the attack soon subsides, and the animal regains its feet within minutes. If the animal is again forced to run, the episode is repeated. Signs are most severe when the animal is heat stressed.

Within flocks and herds, individual susceptibility varies greatly, and this trait is heritable. In outbreaks, morbidity may reach 80%–90%, but mortality is low (0–5%). Deaths are usually accidental, often by drowning when drinking from ponds or streams, or due to the inability to forage for food and water.

The strict seasonal occurrence of characteristic tremors, incoordination, and collapse in several or many animals grazing predominantly perennial ryegrass pastures strongly implicates this disease. Reference to the botanical composition of the pastures will exclude annual ryegrass toxicity (*see* p 3153) and paspalum staggers (*see* p 3019), which have similar clinical signs and seasonality. Microscopic examination of the leaf sheaths of the ryegrass sward will reveal the extent of endophyte infection.

Because movement and handling of animals exacerbates signs, individual treatment is generally impractical. Recovery

is spontaneous in 1–2 wk if animals are moved to nontoxic pastures or crops.

Because the endophyte and the lolitremis and ergovaline are not uniformly distributed within ryegrass plants, control by grazing management can help reduce or prevent the disease. Lolitremis and ergovaline are concentrated in the leaf sheath and inflorescences. If pastures are not overgrazed down into the leaf sheath zone or grazed when the plants are flowering, then animals should be relatively safe even when a high proportion of the ryegrass plants are infected with endophytes. Encouragement of growth of other grass species and legumes in established swards also reduces the intake of toxic grass.

Safe new pastures can be established using ryegrass seed with little or no endophyte infection. Alternatively, seed that has been stored at ambient temperatures for 18–24 mo probably contains few viable endophytes and would produce nontoxic pastures. However, the presence of endophyte in grasses makes the plants resistant to attack from many insects; thus, infected pastures are more persistent than endophyte-free pastures. Cultivars of ryegrass artificially infected with a strain of endophyte that does not produce lolitrem B or ergovaline are available in New Zealand. Signs of ryegrass staggers have not been seen in animals grazing these grasses. A strain of *Neotyphodium* that produces compounds known as epoxy janthetremis has been developed that offers an extended range of pasture insect resistance with the trade-off of sporadic occurrence of low-level staggers.

SORGHUM POISONING

(Sudan grass poisoning)

Sorghum species are drought-tolerant plants that may produce neuropathic and teratogenic manifestations. Sorghum poisoning has been seen primarily in the southwestern USA and Australia. The syndrome is reported almost exclusively in horses, although a similar disease has been reported in sheep and cattle. Lathrogenic nitriles such as β -cyanoalanine, cyanogenic glycosides, and nitrates have been suggested as causative agents. The syndrome develops in horses after they

have grazed hybrid Sudan pastures for weeks to months and produces axonal degeneration and myelomalacia in the spinal cord and cerebellum. (*See also* CYANIDE POISONING, p 2959.) Consumption of the seed will not produce the syndrome.

Sorghum poisoning is characterized by posterior ataxia or incoordination, cystitis, urinary incontinence (which predisposes both male and female horses to cystitis), and alopecia on the hindlegs due to urine scald. The loss of urinary bladder function

is related to degeneration of spinal cord neurons. The incoordination may progress to irreversible flaccid paralysis. Deformities of the fetal musculoskeletal system (ankylosis or arthrogryposis) and abortion may occur during late pregnancy. The diagnosis is based on the analysis of urine for evidence of cystitis, characterization of spinal cord lesions, and analysis of forage for cyanide. Although fatal poisoning is infrequent, the impact on reproduction is

the primary concern. Consumption of sorghum hybrids with low cyanogenic potential or restriction of access to sorghum grasses may limit the incidence. Dietary supplementation with sulfur may be beneficial. Affected horses often die from pyelonephritis. Treatment with antibiotics may be helpful, but a full recovery is rare if ataxia has developed. Consumption of pastures containing sorghum plant species is not recommended for horses.

SWEET CLOVER POISONING

Sweet clover poisoning, an insidious hemorrhagic disease, is seen in animals that consume toxic quantities of spoiled sweet clover (*Melilotus officinalis* and *M. alba*) hay or silage.

Etiology: During the process of spoiling, the coumarins in sweet clover are converted to toxic dicumarol, a potent vitamin K antagonist and anticoagulant. Any method of hay storage that allows molding of sweet clover promotes the likelihood of formation of dicumarol in the hay. Weathered, large round bales, particularly the outer portions, usually contain the highest concentrations of dicumarol. When toxic hay or silage is consumed for several weeks, dicumarol alters proenzymes required for synthesis of prothrombin, resulting in hypoprothrombinemia (by preventing formation of the active enzyme). It probably also interferes with synthesis of factor VII and other vitamin K-dependent coagulation factors (see p 44). Dicumarol concentrations of 20–30 mg/kg of hay ingested throughout several weeks are usually required to cause poisoning in cattle. The toxic agent crosses the placenta in pregnant animals, and newborn animals may be affected at birth. All species of animals studied are susceptible, but instances of poisoning involve cattle and, to a limited extent, sheep, pigs, and horses.

Clinical Findings and Lesions: Clinical signs are referable to hemorrhages that result from faulty blood coagulation. The time between consumption of toxic sweet clover and appearance of clinical disease varies greatly and depends on the dicumarol

content of the particular sweet clover variety being fed, age of the animals, and amount of feed consumed. If the dicumarol content of the ration is low or variable, animals may consume it for months before signs of disease appear.

The first indication of dicumarol poisoning may be the death of one or more animals. In affected animals, the first signs may be stiffness and lameness, due to bleeding into the muscles and joints. Hematomas, epistaxis, or GI bleeding may also be seen. Death is generally caused by massive hemorrhage or bleeding after injury, surgery, or parturition. Neonatal deaths rarely occur without signs in the dam.

Diagnosis: Poisoning occurs when sweet clover hay or silage is consumed continually for relatively long periods. Diagnosis is made by identifying compatible signs and lesions and markedly prolonged blood clotting time or demonstration of reduced plasma prothrombin concentrations. The nature of the coagulopathy can be confirmed in the laboratory when the prothrombin time is prolonged. Sweet clover poisoning is normally a herd problem, making conditions that affect individual animals, such as blackleg, pasteurellosis, bracken fern poisoning, and aplastic anemia, less likely causes.

Rodenticide poisoning (see p 3165) is the primary differential diagnosis in which such large hemorrhages are also likely to occur. Congenital or inherited diseases affecting coagulation factors or blood platelets (eg, hemophilia A) may produce similar large hemorrhages but with largely different morbidity.

Treatment: The hypoprothrombinemia, hemorrhages, and anemia can be immediately corrected, to a degree, by IV administration of whole blood. This may be difficult in large animals, because effective dosages range from 2–10 L of fresh blood per 1,000 lb (450 kg) body wt. Care should be taken to ensure that donor animals are not receiving sweet clover feed. All clinically affected animals should receive a transfusion, which can be repeated if necessary. In addition, all severely affected animals should receive parenteral administration of synthetic vitamin K₁ (phytonadione). SC or IM injection is recommended to avoid the substantial risk of anaphylaxis; SC vitamin K₁ may not be as effective as IM treatment. The usual dosage recommended for cattle is 1 mg/kg, bid-tid for 2 days. Although it is more costly, vitamin K₁ is more effective than K₃ (menadiolone). Because reversal of the dicumarol by vitamin K₁ requires synthesis of coagulation proteins, several hours are required for significant improvement in homeostasis, and >24 hr is required to completely restore coagulation. Either vitamin K₁ or a blood

transfusion is sufficient to correct mild cases if additional exposure is stopped.

Prevention: Cultivars of sweet clover low in coumarin and safe to feed (eg, Polara) have been developed. If one of these is not available, the only certain method of prevention is to avoid feeding sweet clover hay or silage. Although well-cured sweet clover is not dangerous, the absence of visible spoilage is insufficient evidence of safety.

Alternating sweet clover hay suspected of containing dicumarol with other roughage such as alfalfa or a grass-legume hay mixture can be used to avoid severe poisoning. A 7- to 10-day period on the sweet clover hay, followed by an equal time on the alternative hay, can prevent poisoning, but it will not completely prevent prolonged bleeding times. Because some animals have higher risks of serious hemorrhage (surgical candidates or pending parturition), they should not receive sweet clover hay for a minimum of 2–3 wk, and preferably ≥4 wk, before surgery or parturition.

CANTHARIDIN POISONING

(Blister beetle poisoning)

In nature, cantharidin is found in beetles belonging to the Meloidae family. More than 200 species of these beetles are found throughout the continental USA, but members of the genus *Epicauta* are most frequently associated with toxicosis in horses. The striped blister beetles (*E. occidentalis*, *E. texensis*, and *E. vittata*) are particularly troublesome in the southwestern USA. The black blister beetle, *E. pennsylvanica*, has caused toxicosis in horses in Illinois. Cantharidin is the sole toxin, but its concentration in beetles varies widely.

Blister beetles usually feed on various weeds and occasionally move into alfalfa fields in large swarms. These insects are gregarious and may be found in hay in large numbers when it is baled. One flake of alfalfa may contain several hundred beetles, but a flake from the other end of the same bale may have none. Animals are usually exposed by eating alfalfa hay or alfalfa products that have been contaminated with blister beetles.

various organic solvents but only slightly soluble in water. It is highly irritating and causes acantholysis and vesicle formation when in contact with skin or mucous membranes. After ingestion, it is absorbed from the GI tract and rapidly excreted by the kidneys. The minimum lethal oral dose in horses has not been established, but it appears to be <1 mg/kg body wt. As little as 4–6 g of dried beetles may be fatal to a horse. The toxicity of cantharidin does not decrease in stored hay, and cantharidin is also toxic to people, cattle, sheep, goats, dogs, cats, rabbits, and rats.

Clinical Findings: The severity of clinical signs associated with cantharidin toxicosis varies according to dose. Signs may range from mild depression or discomfort to severe pain, shock, and death. Typical signs are related to GI and urinary tract irritation, endotoxemia and shock, hypocalcemia, and myocardial dysfunction. The onset and duration of signs can vary from hours to days. The signs seen most frequently include

Pathogenesis: Cantharidin is an odorless, colorless compound that is soluble in

varying degrees of abdominal pain, depression, anorexia, and frequent attempts to drink small amounts of water or submerge the muzzle in water. Some horses show only signs of depression or make frequent attempts to urinate. Urine may be blood-tinged or contain blood clots but frequently appears normal. A striking feature is that affected horses invariably have dark, congested mucous membranes, even if other systemic signs of toxicosis are minimal. Sweating, delayed capillary refill time, increased heart and respiratory rates, and increased rectal temperature are other common signs. Less frequent signs include oral erosions; salivation; synchronous diaphragmatic flutter; a stiff, short-strided gait; and diarrhea that may contain blood. Horses that ingest a massive amount of toxin may show signs of severe shock and die within hours.

Diagnosis: Both high-performance liquid chromatography and gas chromatography or mass spectrometry analyses are sensitive, reliable methods of detecting cantharidin in gastric contents or in urine. The concentration of cantharidin in urine becomes negligible in 3–4 days, so urine should be collected early in the course of disease if it is to be analyzed. Microscopic evaluation of stomach contents (and often cecal contents) of fatally poisoned horses may reveal fragments of the insect, which

can be positively identified if from one of the three striped species.

Certain laboratory findings are particularly helpful in differentiating cantharidin toxicosis from other causes of acute abdominal crisis. Serum calcium concentration is usually markedly decreased and may remain low for a prolonged time. Serum magnesium concentration is also typically low, and concentration of serum CK usually increases markedly within 24 hr of onset. In acutely affected horses, urinalysis typically reveals markedly decreased specific gravity (usually <1.010) and varying degrees of hematuria. Peritoneal fluid usually contains increased protein (>4 g/dL) but normal numbers of WBCs and normal fibrinogen concentration. Other laboratory abnormalities may include mild increases of serum urea nitrogen and creatinine and development of hypoproteinemia. Acutely affected horses are almost always hyperglycemic.

Treatment: There is no specific antidote for cantharidin poisoning, but prompt, vigorous symptomatic therapy is necessary for a good outcome. Oral administration of mineral oil aids in evacuation of the GI tract, and repeated dosing may be indicated. Activated charcoal, PO, may be helpful if given early. Other oral adsorbents containing ditriooctahedral smectite might be helpful as well, but their efficacy has not been evaluated. Calcium and magnesium supplementation for prolonged periods is almost always indicated. Other symptomatic therapy includes administration of fluids, analgesics, and diuretics and maintenance of normal blood pH and serum electrolyte concentrations. The prognosis for affected horses improves daily if no complications occur.

Prevention: Prevention is by feeding beetle-free hay. The hay field must be scouted before it is cut and during baling, because the insects can be crushed in the cutting and crimping process as well as during baling. Areas of the field that contain swarms of beetles must be avoided for a few days because most of the insects will leave. Once the beetles have left, these areas can be harvested.

First-cutting hay is almost always free of blister beetles, because the insects overwinter as subadults and usually do not emerge until late May or June in the southwestern USA. Likewise, the last cutting of hay is often safe, because it is usually harvested after the adult insects are no longer active.

Epicauta pardalis blister beetle. Courtesy of Dr. D. G. Schmitz.

SNAKEBITE

Venomous snakes of North America are members of either of two families: 1) the Elapidae or coral snakes (*Micrurus* spp); or 2) the Crotalidae, or pit vipers (rattlesnakes [*Crotalus* spp], cottonmouth moccasin [*Agkistrodon piscivorus*], and copperhead [*A. cortotrix*]). Elapids are generally restricted to southern edges of the USA, whereas crotalids are dispersed across the continent. Because of their wider distribution and less secluded natures, bites by crotalids are much more common than elapid bites. Rattlesnakes account for most snakebite-related deaths in people and domestic animals in the USA. Although Australia is home to a large number of venomous snakes from the families Colubridae, Hydrophiidae, and Elapidae, the most clinically significant venomous species are elapids, particularly the black (*Pseudechis*), brown (*Pseudonaja textilis*), Taipan (*Oxyuranus* sp), and tiger (*Notechis scutatus*) snakes.

Crotalids have long, hinged, tubular fangs with which they strike, inject venom (a voluntary action), and withdraw. Many bites by vipers reportedly do not result in injection of substantial quantities of venom and are therefore termed "dry bites." Crotalid venom is typically hemotoxic, necrotizing, and anticoagulant, although a neurotoxic component is present in the venom of some species, eg, the Mojave rattlesnake (*C. scutulatus scutulatus*). North American elapids have short fangs that deliver a neurotoxic venom that paralyzes the respiratory center. Except for death adders (*Acanthophis* spp), the venom delivery system of which resembles that of crotalids, Australian elapids tend to have relatively short, grooved to tubular fangs. The venoms of Australian elapids may have neurotoxic, myotoxic, procoagulant, anticoagulant, and/or hemolytic properties; pronounced cardiovascular abnormalities have been associated with envenomation by tiger and brown snakes.

Fatal snakebites are more common in dogs than in other domestic animals. Because of the relatively small size of some dogs in proportion to the amount of venom injected, the bite of even a small snake may be fatal. In dogs and cats, mortality is generally higher in bites to the thorax or abdomen than bites to the head or extremities. Because of their larger sizes, horses and

cattle seldom die as a direct result of snakebite, but deaths may follow bites on the muzzle, head, or neck when dyspnea results from excessive swelling. Serious secondary damage sometimes occurs; livestock bitten near the coronary band may slough a hoof.

Snakebite with envenomation is a true emergency. Rapid examination and appropriate treatment are paramount. Owners should not spend time on first aid other than to keep the animal quiet and limit its activity. The following commonly touted measures are ineffective and can be potentially harmful: use of ice, cold packs, or sprays; incision and suction; tourniquets; electric shock; hot packs; and delay in presentation for medical treatment (waiting until problems develop).

Diagnosis: In many instances, the bite has been witnessed, and diagnosis is not a problem. However, fractures, abscesses, spider envenomations (see p 3162), or allergic reactions to insect bites or stings could all potentially be confused with a snakebite by the inexperienced eye. When possible, the *dead* snake should be brought along with the bitten animal; mutilation of the snake's head should be avoided, because this may hinder proper identification. Some bites do not result in envenomation or have been made by nonvenomous snakes. In Australia, venom detection test kits have been developed to detect the various snake venoms and determine the appropriate antivenom to use, but these appear to be infrequently used for veterinary patients.

Typical crotalid bites are characterized by severe local tissue damage that spreads from the bitesite. The tissue becomes markedly discolored within a few minutes, and dark, bloody fluid may ooze from the fang wounds if not prevented by swelling. The epidermis may slough when the overlying hair is clipped or parted. Hair may hide the typical fang marks. Sometimes, only one fang mark or multiple punctures are present. Neurologic signs, including muscle fasciculations, are possible if neurotoxic crotalid venom is involved. In elapid snakebites, pain and swelling are minimal, and systemic neurologic signs predominate. Signs of coral snake envenomation include tetraparesis, ptyalism, tachypnea, shallow/abdominal breathing, depressed gag reflex, ataxia, muscle fasciculation, decreased spinal reflexes, and quiet mentation. Australian

elapid bite victims may show collapse, vomiting, ptialism, tremors, tachypnea, urinary and/or fecal incontinence, tetraparesis, hemolysis, coagulopathy, rhabdomyolysis, swelling at the bite site, renal failure, and/or delayed immune-mediated hemolytic anemia (red-bellied black snake).

Treatment: Intensive therapy should be instituted as soon as possible, because irreversible effects of venom begin immediately after envenomation. The bite site(s) should be shaved, and the wounds cleansed thoroughly with germicidal soap. For animals bitten by crotalids, the leading edge of tissue swelling should be marked on the skin with a magic marker at frequent intervals to monitor the spread of tissue injury. All snakebite victims should be monitored closely for a minimum of 24 (crotalid) to 48 (elapid) hr for the development of clinical signs.

Treatment for crotalid envenomation should be directed toward preventing or controlling shock, neutralizing venom, preventing or controlling coagulopathy, minimizing necrosis, and preventing secondary infection. Any dog or cat presented within 24 hr of a snakebite showing signs of crotalid envenomation requires intensive treatment, starting with IV crystalloids to combat hypotension. Rapid-acting corticosteroids may be of benefit in the first 24 hr to help control shock, protect against tissue damage, and minimize the likelihood of allergic reactions to antivenin; however, prolonged use of corticosteroids is not recommended. Monitoring for the development of echinocytes or coagulopathy is recommended, because these are often early signs of severe envenomation.

Antivenom is the only direct and specific means of neutralizing snake venom. Antivenoms available against North American pit vipers include equine-derived polyvalent antivenin, ovine-origin polyvalent F(ab) fragment antivenin, and equine-origin polyvalent F(ab)² fragment antivenin. The F(ab) antivenins use the F(ab) components of the immunoglobulin molecule, resulting in an antivenin that has lower risk of allergic reaction, faster reconstitution, and potency similar to that of the polyvalent immunoglobulin. Antivenin is most effective if administered in the first 6 hr after the bite, although improvement in clinical condition may be seen after antivenin administered ≥ 24 hr after the bite. In the unlikely event of an anaphylactic reaction to the antivenin, 0.5–1 mL of 1:1,000 epinephrine, with or without antihistamines such as diphenhy-

dramine, should be administered SC. In severe envenomations, multiple vials of antivenom/antivenin may be required, although this is frequently cost-prohibitive in veterinary patients.

Antivenin generally helps significantly in managing the pain of a crotalid bite, but opioid analgesics may be used as needed for residual pain. If coagulopathy (thrombocytopenia, disseminated intravascular coagulation, etc) occurs, appropriate treatment, including blood replacement products and heparin sodium (in mini dose at 5–10 U/kg/hr or low dose at 50–100 U/kg, SC, tid), should be administered. Hemoglobin glutamer-200 (bovine) or hetastarch may be helpful to manage hypovolemia; however, colloids should be used with caution because of their potential to leak out of damaged vessels and pull fluids into tissue beds.

Several potential pathogens, including *Pseudomonas aeruginosa*, *Clostridium* spp, *Corynebacterium* spp, and staphylococci have been isolated from the mouth of rattlesnakes. However, the incidence of wound infection after snake bites is low, and many clinicians use antibiotics only when significant tissue necrosis is present. Broad-spectrum antibiotics such as amoxicillin/clavulanate or cephalosporins are preferred.

Tetanus antitoxin also should be considered, especially in horses, and other supportive treatment should be administered as needed (eg, blood or plasma transfusions in the case of hemolytic or anticoagulant venoms). In most cases, surgical excision of tissue is impractical or unwarranted. Antihistamines have been reported to be contraindicated, but diphenhydramine hydrochloride (10–50 mg, SC or IV) has been shown to be helpful to manage fractious patients and may possibly assist in minimizing risk of allergic reactions to antivenin.

Animals bitten by elapids may be treated with supportive care as needed (IV fluids, ventilatory support, anticonvulsants, etc) and antivenom/antivenin, if available. Ventilatory support is frequently required for 6–8 hr in animals experiencing Australian elapid envenomation; additional vials of antivenom can reduce ventilator time. Antivenom against coral snake venoms is no longer being manufactured in the USA, although some practitioners have received special permission to import coral snake antivenom from Mexico. In Australia, several antivenoms/antivenins are available for use in veterinary patients. A polyvalent antivenin is available for use when the

identity of the snake cannot be ascertained, and many clinicians prefer to use the polyvalent antivenin for all envenomations. Additionally, animals bitten by Australian elapids should be monitored for development of coagulopathy, hemolysis, renal injury, cardiovascular abnormalities, or rhabdomyolysis; appropriate treatment should be instituted as needed. As with crotalid bites, broad-spectrum antibiotics may be indicated if there is risk of infection of the bite wound.

Prognosis: The prognosis of snakebite depends on the type and species of snake, location of the bite, size of the victim, degree of envenomation, and the time interval between the bite and the institution of treatment. Animals that survive elapid bites generally make full recoveries, but crotalid bites can result in long-term sequelae due to tissue necrosis (amputation, loss of function, etc), depending on the severity of the bite and the promptness and aggressiveness of treatment instituted.

TOAD POISONING

Dogs and, less frequently, cats may be poisoned by oral exposure to many types of toads. Severity varies greatly, depending on extent of contact and type of toad. Toxins are produced by all toads, but potency varies with species and apparently between geographic locations within individual species. Toad toxin, a defensive mechanism, is secreted by large glands located dorsal and posterior to the eyes and by smaller glands distributed throughout the skin. The toxin, a thick, creamy white, highly irritating substance, can be expelled quickly by the contraction of periglandular muscles in the skin. Its many components include bufagenins, which have digitalis-like effects, and bufotoxins, which block sodium channels in nerves similar to the actions of local anesthetics, catecholamines, and serotonin. The most toxic species in the USA is the giant or marine toad, *Rhinella marina* (formerly *Bufo marinus*), an introduced species that is established in Florida, Hawaii, and Texas. *R. marina* is also known as the cane toad in Australia, where its range extends across the northeastern half of the continent. Mortality ranges from 20%–100% in untreated cases, depending on exposure circumstances. The Colorado River toad, *Incilius* (formerly *Bufo*) *alvarius*, found in the southwestern USA and northern Mexico, is another toad of sufficient size to have potentially lethal levels of toxins in its skin secretions.

Clinical Findings and Diagnosis:

Encounters with toads are most common in warm or mild weather. Signs of poisoning are variable and range from local effects to

convulsions and death. Severity depends on host factors, extent of exposure, length of time since exposure, and species of toad. Local effects (profuse, sometimes frothy salivation, accompanied by vigorous head shaking, pawing at the mouth, and retching) are immediate, probably because the toxin is extremely irritating. Vomiting is not unusual, especially in severe cases, and although it may persist for several hours, no further signs may develop in poisoning by common indigenous toads. With more severe intoxication, as from *R. marina* or *I. alvarius*, cardiac arrhythmias, dyspnea, cyanosis, and seizures are characteristic. Cardiac and CNS involvement can be life-threatening.

Treatment: A specific antidote for toad toxins is not available. Therapy is directed at minimizing toxin absorption and controlling associated clinical signs. Minimal treatment may be required after exposure to toxins in areas where less toxic toads are found. The mouth should be immediately and thoroughly flushed with copious amounts of water. Affected animals should be prevented from inhaling aerosols of saliva or water that contain toad toxin. Atropine may reduce the volume of saliva and the risk of aspiration but should not be used until cardiovascular status is assessed. More severely affected animals require more extensive therapy. Cardiac arrhythmias should be identified and controlled using standard treatment protocols (see also ARRHYTHMIAS, p 90). If bradyarrhythmias exist, atropine or dopamine should be considered;

tachyarrhythmias should be treated with lidocaine, phenytoin, propranolol, or procainamide hydrochloride. Digoxin-specific Fab may be considered in cases of severe arrhythmias refractory to standard antiarrhythmic therapy. CNS excitation, if present, should be controlled by benzodi-

azepines, barbiturates, or a combination of the two. Anesthetics that predispose to ventricular fibrillation (eg, halothane) should be avoided. Supplemental oxygen and mechanical ventilation may also be needed if cyanosis and dyspnea are prominent.

VENOMOUS ARTHROPODS

Envenomation of animals by poisonous arthropods is relatively uncommon and difficult to recognize. It may be suspected relative to presenting clinical signs, but confirmatory evidence is rare because of the inability to capture the offending arthropod.

SPIDERS AND SCORPIONS

Spiders of medical importance in the USA do not inflict particularly painful bites, so it is unusual for a spider bite to be suspected until clinical signs appear. It is also unlikely that the spider will remain in close proximity to the victim for the time required for signs to develop (30 min to 6 hr). Almost all spiders are venomous, but few possess the attributes necessary to cause clinical envenomation in mammals—mouth parts of sufficient size to allow penetration of the skin and toxin of sufficient quantity or potency to result in morbidity.

The spiders in the USA that are capable of causing clinical envenomation belong to two groups: widow spiders (*Latrodectus* spp) and brown spiders (mostly *Loxosceles* spp).

Widow Spiders: Widow spiders usually bite only when accidental skin contact occurs. The most common species is the black widow spider, *Latrodectus mactans*, characterized by a red hourglass shape on its ventral abdomen. In the western USA, the western black widow, *L. hesperus*, predominates, while the brown widow, *L. bishopi*, is found in the south, and the red widow, *L. geometricus*, is found in Florida.

Venom from these spiders is one of the most potent biologic toxins. The most important of its five or six components is a neurotoxin that causes release of the neurotransmitters norepinephrine and

acetylcholine at synaptic junctions, which continues until neurotransmitters are depleted. The resulting severe, painful cramping of all large muscle groups accounts for most of the clinical signs attributed to envenomation.

Unless there is visual confirmation of a widow spider bite, diagnosis must be based on clinical signs, which include restlessness with apparent anxiety or apprehension; rapid, shallow, irregular respiration; shock; abdominal rigidity or tenderness; and painful muscle rigidity, sometimes accompanied by intermittent relaxation (which may progress to clonus and eventually to respiratory paralysis). Partial paresis also has been described.

An antivenin (equine origin) is commercially available but is usually reserved for confirmed bites of high-risk individuals (very young or very old). Symptomatic treatment is usually sufficient but may require a combination of therapeutic agents. Calcium gluconate IV (10 mL of a 10% solution is the usual human dose) is reportedly helpful. Meperidine hydrochloride or morphine, also given IV, provides relief from pain and produces muscle relaxation. Muscle relaxants and diazepam are also beneficial. Tetanus antitoxin also should be administered. Recovery may be prolonged; weakness and even partial paralysis may persist for several days.

Brown Recluse Spiders: There are at least 10 species of *Loxosceles* spiders in the USA, but the brown recluse spider, *L. reclusa*, is the most common, and envenomation by it is typical for the genus. These spiders have a violin-shaped marking (or "fiddleback") on the spider's dorsum, the cephalothorax, although it may be indistinct or absent in some species. In the northwestern USA, the unrelated spider *Tegenaria*

agrestis reportedly causes a clinically indistinguishable dermonecrosis in people and presumably in domesticated animals. Brown recluse spider venom has vasoconstrictive, thrombotic, hemolytic, and necrotizing properties. It contains several enzymes, including a phospholipase (sphingomyelinase D) that attacks cell membranes. Pathogenetic mechanisms of the characteristic dermal necrosis are poorly understood, but activation of complement, chemotaxis, and accumulations of neutrophils affect (or amplify) the process.

A history of a bite by a brown recluse spider is useful but rare. A presumptive diagnosis may be based on the presence of a discrete, erythematous, intensely pruritic skin lesion that may have irregular ecchymoses. Within 4–8 hr, a vesicle develops at the bite wound, and sometimes a blanched zone surrounds the erythematous area, producing a “bull’s-eye” appearance to the lesion. The central area sometimes appears pale or cyanotic. The vesicle may degenerate to an ulcer that, unless treated in a timely manner, may enlarge and extend to underlying tissues, including muscle. Sometimes, a pustule follows the vesicle and, on its breakdown, a black eschar remains. The final tissue defect may be extensive and indolent and require months to heal. However, medical authorities claim that not all brown recluse spider bites result in severe, localized dermal necrosis.

Systemic signs sometimes accompany brown recluse spider envenomation and may not appear for 3–4 days after the bite. Hemolysis, thrombocytopenia, and disseminated intravascular coagulation are more likely to occur in cases with severe dermal necrosis. Fever, vomiting, edema, hemoglobinuria, hemolytic anemia, renal failure, and shock may result from systemic loxoscelism.

In known spider bites, early treatment can be successful, but unfortunately, many cases are not recognized until cutaneous necrosis has become extensive; treatment at that stage is less rewarding but is still of value. Immediate application of cold packs is beneficial, and if administered early, corticosteroids protect against cutaneous necrosis by stabilizing cell membranes and suppressing chemotaxis. Corticosteroids also tend to protect against systemic involvement. Radical excision has been advocated, but its value is questionable. Dapsone, an inhibitor of leukocyte function, which is frequently used in the treatment of leprosy, is currently considered the drug of choice for brown

recluse spider bites. In people, it is administered at 100 mg, bid, for 14–25 days. Broad-spectrum antibiotics are useful in preventing secondary infection, and tetanus immunoprophylaxis should be considered.

Tarantulas: Tarantulas (many assorted genera and species) are common throughout the USA and South America. They are increasingly being kept as household pets throughout the world. Along with many other exotic arthropods, they are frequently sold in exotic pet stores.

Tarantulas should not be mixed with or allowed contact with other domesticated pets. Fine hairs (setae), present over much of the tarantula’s abdomen, may be discharged (or cast off) by the tarantula as a defense mechanism against larger creatures. If these fine hairs make contact with unprotected skin, they can produce contact allergic reactions. Care must be taken to keep these fine hairs from entering the eye, particularly the cornea, because they can be quite difficult to remove. In addition, the bite of the tarantula can be fatal to dogs or cats, which are very susceptible to tarantula venom. Safety of the tarantula is another reason to keep these spiders separated from other pets, because a dog or cat can easily injure or kill a pet tarantula.

Scorpions: Most of the scorpions found throughout the USA possess posterior abdominal stingers that connect to venom glands. The stinger and its associated venom can be used both as mechanisms of self-defense and of predation. For the most part, the stings of these scorpions are considered to be innocuous in most domesticated mammalian species, because the amount of venom is too minute or the venom has very little pharmacologic potency. The sting of these arthropods is analogous to an insect sting/bite, with pain and swelling at the site of the injury.

Relative to pharmacologically potent scorpion stings in domesticated animals, there are two geographic scenarios of veterinary clinical importance. The first involves *Centruroides sculpturatus*, commonly known as the Arizona bark scorpion. This venomous arthropod can be found in all counties of Arizona, into western New Mexico, southern Utah, southern Nevada to the Las Vegas vicinity, California along the Colorado River (where it is rare), and down to the area of the state of Sonora, Mexico. It has been reported to produce envenomation in dogs; however, its sting is similar to that of the venomous hymenopterans, producing

local pain and swelling with the possibility of associated hypertension. Most animals recover without a problem, but more severe reactions are possible.

The second scenario involves myriad geographic locales (eg, desert-like and jungle ecosystems) throughout the world where many venomous scorpions abound. People with penchants for hiking the world should be warned to be wary of visits to these areas, and traveling with canine companions in such scenarios should be strongly discouraged.

HYMENOPTERA

Honey Bees, Wasps, Hornets, and Yellow Jackets:

There are many venomous hymenopterans (eg, honey bees, wasps, hornet, yellow jackets), in which the female drone possesses a barbed ovipositor on the tip of the abdomen that connects to paired venom glands. Bees possess a barbed stinging apparatus; after stinging the victim, bees die because the stinger and its associated venom sac are pulled out of the abdomen. Wasps, hornets, and yellow jackets possess a stinging apparatus that is not barbed; they are capable of stinging multiple times. The venom glands of honeybees contain a hydrolyzing protein, mast cell degranulating peptides, a phospholipase, hyaluronidase, vasoactive amines, and a neurotoxin apamin.

A single bee sting will produce pain, swelling, erythema, edema, and local induration, which can be followed by pruritus at the injection site. The incidence of anaphylactic reactions is not known in companion animals—if a severe systemic reaction has not occurred within 30 min, it is not likely to occur. In dogs, bee and wasp stings cause only local redness, erythema, and transient pain. Dogs may vocalize when stung and may rub their mouth and eyes on the ground. Usually cutaneous reactions appear quickly and regress spontaneously. With repeated stings, anaphylaxis, with salivation, vomiting, diarrhea, circulatory collapse, pallor, or cyanosis, may result (see p 823).

The stinger/ovipositor (if present) with accompanying venom glands should be removed, if it can be located. In severe cases with urticaria, epinephrine should be given IM. In cases of anaphylaxis, epinephrine should be immediately administered, SC, at a dosage of 1:1,000 (0.1–0.5 mL) for dogs or cats. This dosage can be repeated every 10–20 min. When given IV, it must be diluted to 1:10,000, and 0.5–1 mL is administered

with vigilant monitoring of heart rate, heart rhythm, and blood pressure. IV fluids are indicated to prevent vascular collapse. Antihistamines and corticosteroids should also be given. The animal may require intubation to provide supplemental oxygen.

Africanized Honeybees (“Killer Bees”):

The common honeybees in America were brought to the New World by European settlers; as a result, the European varieties of honeybees established themselves throughout North and South America. In the 1950s, African colonies of bees were crossed with the docile European varieties of honeybees in laboratories in Brazil, but their offspring managed to escape from the laboratory environment. These hybridized offspring were characterized by excitability, aggressive defense of the hive, and frequent swarming activity. Since their escape in 1957, these “killer bees” have spread throughout most of South America, through Central America and Mexico, and into the southern regions of the USA; their range is expected to expand northward.

Africanized bees are difficult to distinguish morphologically from their European counterparts. Their stinging behavior is primarily defensive, eg, in response to a perceived threat to the colony. These bees habitually sting en masse. Once initiated, stinging recruitment within the colony can result in hundreds or thousands of stings; bees may pursue their victim for as far as 1 km. Hives are generally found in exposed locations such as on tree branches or in old tires or boxes where domesticated animals may come in contact with them. Stings occur generally in the vicinity of the hive. Smaller pets are particularly susceptible to the effects of multiple stings, because they receive a larger dose of venom/kg body wt. It is the cumulative dose of venom that becomes fatal.

Animals that receive massive envenomations are visibly depressed and usually febrile. They may exhibit facial paralysis, ataxia, seizures, and neurologic signs. The urine may be dark brown or red, and the feces are bloody. Bloody or dark brown vomitus may be seen. Leukocytosis may be present. The animal may be thrombocytopenic; disseminated intravascular coagulation may be imminent. Urinalysis may reveal granular casts due to renal tubular damage. The animal may develop acute renal failure caused by acute tubular necrosis or direct toxic effect of massive envenomation. Dogs may develop a secondary immune-mediated hemolytic anemia.

Access to cardiac monitoring, supplemental oxygen, "crash cart" drugs, and airway intubation must be readily available. Any animal that receives massive, multiple stings must be hospitalized, treated aggressively, and hospitalized for 24 hr after cessation of clinical signs.

Fire Ants: Fire ants (red imported fire ants and black imported fire ants) are not native to North America but were introduced into the USA in the early years of the 20th century. Since their introduction, red imported fire ants (*Solenopsis invicta*) have colonized more than 310 million acres in 12 southern states, whereas black imported fire ants (*S. richteri*) have been contained in a small area in Alabama and Mississippi. Fire ants attack domestic animals and native wildlife. The ant anchors onto its victim with its prominent mandibles, tucks its abdomen under its body, and stings with its nonbarbed stinger, a modified ovipositor with an associated venom gland. It retracts its stinger, rotates its body to the side, and stings again. This act is repeated in a circular pattern. Unlike bees, wasps, and hornets, fire ants inject their venom slowly. Each ant can deliver 0.11 μ L with a total of 20 consecutive stings before the venom gland is depleted.

The typical reaction to a fire ant sting is a wheal and flare, which usually resolves within an hour. Pain and inflammation begin

immediately. A papule will form at the sting site and develop into a sterile pustule. These pustules are pruritic and may become secondarily infected due to self-inflicted trauma. Regional reactions can occur and may be erythematous, indurated, and quite pruritic. Regional edema may be severe enough to impede blood flow to a limb. Systemic or anaphylactic reactions can produce clinical signs removed from the site of the initial sting, including urticaria, cutaneous edema, laryngeal edema, bronchospasm, vascular collapse, and death. Deaths due to systemic anaphylaxis occur within minutes of the sting, whereas deaths due to venom toxicity occur >24 hr after the sting.

There are no treatments to prevent or resolve localized reactions to fire ant stings; however, symptomatic therapy might be beneficial. Local reactions may be treated with antihistamines, topical corticosteroids, water or alcohol compresses, ice, and topical treatment with menthol and camphor. Warm baths may provide some relief for dogs. Regional reactions occur less frequently and should be treated with antihistamines, corticosteroids, analgesics, and fluid therapy. Antibiotics are indicated for secondary infections. Anaphylactic reactions to fire ant stings are treated similarly to those from honeybees, wasps, and yellow jackets (*see above*).

RODENTICIDE POISONING

Many poisons have been used against rodent pests. If baits are not well secured, they may be ingested directly by nontarget animal species (farm animals, pets, and wildlife). Sometimes, nontarget species may ingest recently poisoned rodent pests and develop relay or secondary poisoning. Occasionally, baits may be used maliciously or intentionally to kill either domestic animals or wildlife. This chapter discusses only the most commonly used rodenticides currently available in the market: anticoagulants, bromethalin, cholecalciferol, and zinc phosphide. Strychnine poisoning (*see* p 3170) is discussed separately.

Whenever a rodenticide exposure is suspected, owners should be asked history

questions to determine the day and time of exposure, brand name and manufacturer of rodenticide, active ingredients and their concentration, package size, and the potential amount missing. The Environmental Protection Agency (EPA) registration number is the most accurate way to confirm identity of an active ingredient. There is no way to identify differing class by color, shape, or size of a bait.

ANTICOAGULANT RODENTICIDES (WARFARIN AND CONGENERS)

Anticoagulant rodenticides inhibit the enzyme vitamin K epoxide reductase, which normally reactivates vitamin K, a crucial component in a number of normal clotting

factors, after those factors are consumed in normal maintenance. Potentially dangerous to all mammals and birds, anticoagulant rodenticides are a common cause of poisoning in pets and wildlife. Intoxications in domestic animals have resulted from contamination of feed with anticoagulant concentrate, malicious use of these chemicals, and feed mixed in equipment used to prepare rodent bait.

All anticoagulants have the basic coumarin or indanedione nucleus. The "first-generation" anticoagulants (warfarin, pindone, coumafuryl, coumachlor, isovaleryl indanedione, and others less frequently used) require multiple feedings to result in toxicity. The "intermediate" anticoagulants (chlorophacinone and in particular diphacinone) require fewer feedings than "first-generation" chemicals, and thus are more toxic to nontarget species. The "second-generation" anticoagulants (brodifacoum, bromadiolone, difethiolone) are highly toxic to nontarget species (dogs, cats, livestock, or wildlife) after a single feeding. Secondary poisoning in nontarget animal species from anticoagulants has also been documented. The concentration of brodifacoum and bromadiolone in the bait available as pellets or blocks is usually 0.005% and that of difethiolone 0.0025%.

Anticoagulants antagonize vitamin K, which interferes with the normal synthesis of coagulation proteins (factors I, II, VII, IX, and X) in the liver; thus, adequate amounts are not available to convert prothrombin into thrombin. A latent period, dependent on species, dose, and activity, is required, during which clotting factors already present are used up. New products have a longer biologic half-life and therefore prolonged effects (which require prolonged treatment). For example, the half-life in canine plasma of warfarin is 15 hr, diphacinone is 5 days, and

bromadiolone is 6 days, with maximum effects estimated at 12–15 days. Brodifacoum may continue to be detectable in serum for up to 24 days. All of these may be detected in liver even after serum levels drop.

Clinical signs generally reflect some manifestation of hemorrhage, including anemia, hematomas, melena, hemothorax, hyphema, epistaxis, hemoptysis, and hematuria, any of which may lead to weakness, ataxia, colic, polypnea, etc. Petechiae rarely develop until after repeated small bleeds have consumed too many platelets. Depression and anorexia may be seen in all species even before bleeding occurs. Typically, the onset of clinical signs is delayed (due to consumption of vitamin K–dependent clotting factors) for 3–7 days after exposure (can be a little earlier with a fairly large dose). Dogs can also show nonspecific clinical signs, such as limping or swollen joints (due to hemorrhage in the joints), coughing or wheezing (bleeding in the lungs), bulging of eyes (retrobulbar hemorrhages), and pale mucous membrane color. Sudden death with no obvious clinical signs is also possible.

Anticoagulant rodenticide toxicosis may be diagnosed based on history of availability of the bait in the animal's environment and evidence of exposure (missing or chewed up package/bait, passing of greenish blue feces [color of the bait]) but cannot be discounted if there is no known history of exposure. Differential diagnoses when hemorrhage is encountered include disseminated intravascular coagulation, congenital factor deficiencies, von Willebrand disease, platelet deficiencies, and canine ehrlichiosis. A prolonged prothrombin time (PT), activated partial thromboplastin time (APTT), or thrombin time in the presence of normal fibrinogen, fibrin degradation products, and platelet counts is strongly suggestive of anticoagulant rodenticide toxicosis, as is a positive therapeutic response to vitamin K₁. Stomach contents, serum, or plasma can be analyzed for the presence of anticoagulant to confirm a diagnosis. Most veterinary diagnostic laboratories have an "anticoagulant screen" to detect most of the anticoagulants available in the market in the serum, plasma, liver, or kidney.

Vitamin K₁ is antidotal. Because the vast majority of exposures are to the second-generation agents, recommended dosages are generally 3–5 mg/kg/day, PO, for 3–4 wk. Treating for an extra week will not be harmful, whereas discontinuing treatment too soon can be lethal. The best way to

Anticoagulant rodenticide poisoning, thorax hemorrhage. Courtesy of Dr. Frederick W. Oehme.

know when to stop vitamin K₁ treatment is by checking the PT time 72 hr after the last dose of vitamin K₁ has been given. If PT at that point is normal, treatment with vitamin K₁ can be stopped; if it is still prolonged, treatment with vitamin K₁ for 1 more week is warranted. The doses should be administered with small amounts of fatty food (milk, meat, or cheese), because fat will enhance vitamin K₁ absorption. Administering half of the daily dose every 12 hr will provide more constant levels of vitamin K₁. In animals exhibiting clinical signs when coagulation factors are abnormal, it is probably safer to avoid injections (unless the animal is unable to take vitamin K₁ orally) because of the risk of bleeding and hematoma formation at the injection site. Also, the possibility of anaphylactoid reaction cannot be excluded when vitamin K₁ injection is administered parentally.

Fresh or frozen plasma (9 mL/kg) or whole blood (20 mL/kg) IV may be indicated to replace needed clotting factors and RBCs immediately if bleeding is present. Administration of oxygen may be very useful. Activity should be limited as much as possible during the first week of therapy to minimize bleeds due to trauma to tissues. Oral vitamin K₁ alone (3–5 mg/kg, PO) can be used to prevent coagulopathy after a known exposure to an anticoagulant.

If a coagulopathy has developed, rechecking the PT and APTT every 24 hr until normalized should be considered. At the end of a course of vitamin K₁ supplementation, a coagulation profile is needed ~48–72 hr after the last dose to confirm that no indication of coagulopathy remains.

Vitamin K₃ given as a feed supplement is ineffective in treatment of anticoagulant rodenticide toxicosis. Administration of vitamin K₃ by injection in horses has been associated with acute renal failure and is never an appropriate treatment.

To increase protection to nontarget animal species and children, the US EPA has promulgated new rules on packaging and availability of anticoagulants. Some of the highlights of these new rules include the following:

- 1) Consumer products available in retail, hardware, grocery, or convenient stores with under a pound of bait can no longer contain second-generation anticoagulants (brodifacoum, difethialone, bromadiolone, or difenacoum).
- 2) Only first-generation anticoagulants (warfarin, diphacinone, chlorophacinone) or rodenticides other

- than anticoagulants (bromethalin, cholecalciferol) are allowed for sale in retail stores for use by consumers.
- 3) All outdoor, above-ground use must be in a bait station intended to be resistant to children and pets.
- 4) Loose poison baits (pellets, meals) are prohibited.
- 5) All outdoor products are to be placed within 50 feet of a building.
- 6) Professional use products are available in quantities of at least 8 or 16 pounds (second-generation anticoagulants) or at least 4 pounds (first-generation anticoagulants); they are to be placed in bait stations.
- 7) Professional class anticoagulants (second-generation) are not to be marketed in “consumer” stores (grocery, hardware, or club stores).

The possible unintended end result of these new EPA regulations is likely to be a higher incidence of exposure to rodent baits that contain either bromethalin or cholecalciferol (vitamin D₃).

BROMETHALIN

Bromethalin, a nonanticoagulant, single-dose rodenticide, is a neurotoxin available as bars (blocks), pellets, seed, and worm. Mole baits are sold as worm containing 0.025% bromethalin, whereas rat and mouse baits contain 0.01% bromethalin. Bromethalin and its main metabolite desmosebromethalin are strong uncouplers of oxidative phosphorylation. This results in intra-myelin fluid accumulation, leading to long nerve demyelination and intra-myelin cerebral edema. The net result is cerebral and spinal edema and increased CSF pressure, leading to neurologic dysfunction. In toxicity trials, the oral toxic dose of bromethalin when used as part of bait appears to be much lower than the dose administered as a technical grade agent. For example, in dogs, an average lethal dose of technical grade bromethalin is reported to be 4.7 mg/kg but 2.38 mg/kg in bait. Young dogs (<1 yr old) appear more sensitive; death has been reported at dosages of ~1 mg/kg in bait. Dogs are more commonly involved. Cats are 2–3 times more sensitive than dogs.

Bromethalin can cause either an acute or a subacute/chronic syndrome, depending on the dose ingested. At doses equivalent to or more than the average lethal dose, dogs may develop an acute convulsant (or high-dose) syndrome resulting in clinical signs within 4–36 hr of exposure; such signs include hyperexcitability, muscle tremors, grand mal seizures, hindlimb hyperreflexia, CNS

depression, hyperthermia, and death. The paralytic (subacute or chronic) syndrome is seen at lower doses, and clinical signs may not appear for several days (up to 7 days) after exposure. Initial signs may include depression, hindlimb weakness or paresis, decreased proprioception, ataxia, and possible tremors. Muscle weakness often progresses from posterior to anterior muscles. Cats typically develop paralytic syndrome irrespective of dose of bromethalin.

Presumptive diagnosis of bromethalin toxicosis is made based on known or suspected history of exposure to the bait, followed by development of neurologic signs within 1–7 days of exposure. Diagnosis can be confirmed by detecting the presence of bromethalin or its major metabolite in liver, kidney, brain, or fat; this analysis is available only in some veterinary diagnostic laboratories in the USA.

Based on the history of exposure, bromethalin toxicosis should be considered when there is moderate to acute onset of weakness, hindlimb paralysis, tremors, and seizures. Some other toxicologic and nontoxicologic differential diagnoses should include ethylene glycol toxicosis, marijuana ingestion, 2,4-D and other phenoxyacetic acid herbicide toxicosis, copper head snake envenomation (cats), intervertebral disc problems, spinal cord and CNS trauma, and tick paralysis.

Treatment of bromethalin toxicosis is aimed at early decontamination (induction of emesis and administration of activated charcoal) in an asymptomatic animal and controlling CNS signs (seizures) and providing supportive care in a symptomatic animal. Emesis using 3% hydrogen peroxide solution or apomorphine in dogs and xylazine in cats within 4 hr of ingestion may remove some bait from the gut. Depending on the ingested dose of bromethalin, administration of activated charcoal is considered an effective method to prevent toxicosis. Bromethalin undergoes enterohepatic recirculation, so administration of repeated doses of activated charcoal may be helpful.

The following can be used as a guideline to treat bromethalin exposure in dogs and cats:

At a bromethalin dosage of 0.1–0.49 mg/kg in dogs, or 0.05–0.1 mg/kg in cats, emesis alone within 4 hr of exposure may be adequate. If emesis is not successful, or if > 4 hr have elapsed since ingestion, a single dose of activated charcoal at 1–2 g/kg body wt is indicated. Whenever administering activated charcoal, the clinician must remain aware of the risk of aspiration or hyponatremia secondary to

fluid shift into the gut. The clinical signs of acute hyponatremia may mimic those seen with bromethalin toxicosis.

At a bromethalin dosage of 0.5–0.75 mg/kg in dogs, or 0.1–0.3 mg/kg in cats, an initial dose of activated charcoal at 1–2 g/kg body wt should be considered. A repeat dose at half the original dose at 8-hr intervals for a total of three doses can be administered, again being aware of and monitoring for possible hyponatremia.

At a bromethalin dosage of ≥ 0.75 mg/kg in dogs, or ≥ 0.3 mg/kg in cats, administration of six doses of activated charcoal over 48 hr (repeat every 8 hr) can be considered to reduce the body burden by interrupting enterohepatic recirculation.

Use of mannitol and corticosteroids has been suggested to treat clinical signs, because they may help manage cerebral edema due to other causes. However, this has not been shown to be very helpful, likely because of the presence of intra-myelin edema. Diazepam, barbiturates, and other anticonvulsant medications should be used to control seizures and other CNS signs. Full recovery may require days to weeks of treatment.

CHOLECALCIFEROL

Cholecalciferol (vitamin D₃) is used both as a dietary supplement and a rodenticide. It appears to be toxic at a much lower dose when consumed in a bait form than when ingested as a technical grade agent. Most rodenticide baits contain 0.075% cholecalciferol. Incidence of vitamin D₃ toxicosis in animals is relatively less than that of anticoagulant and bromethalin toxicosis. Relay toxicosis from vitamin D₃ has not been documented. One international unit (1 IU) of vitamin D₃ in nutritional supplement is equivalent to 0.025 mcg of cholecalciferol.

Cholecalciferol toxicosis is characterized by hyperphosphatemia and hypercalcemia, leading to renal failure, cardiac abnormalities, hypertension, CNS depression, anorexia, vomiting, diarrhea, and lethargy. The increased calcium and phosphorus can lead to calcification of soft tissue, notably the highly vascular areas of kidneys and lungs, as well as within the walls of the great blood vessels.

Clinical signs generally develop within 18–36 hr of ingestion; initial signs can include depression, anorexia, polyuria, and polydipsia. The serum phosphorus more commonly rises first, at ~12–24 hr after ingestion, with serum calcium levels rising within another 12–24 hr. Nausea, vomiting, hematemesis, and depression are common

as the clinical signs progress. It is important to obtain a baseline biochemistry profile as early as possible after the exposure, so that each animal can be monitored based on individual values.

Ingestion of vitamin D₃ at >0.1 mg/kg may require decontamination (induction of emesis and administration of activated charcoal) and monitoring of serum calcium, phosphorus, and renal values. Emesis can be induced within 2 hr of exposure with 3% hydrogen peroxide or apomorphine in dogs and xylazine in cats. Activated charcoal at 1–2 g/kg is an appropriate initial dose for decontamination, and a second half dose after ~6–8 hr may be helpful. In addition, use of cholestyramine, a bile acid sequestrant, may be useful to decrease the body burden of vitamin D₃ that undergoes enterohepatic recirculation with bile acids. However, the efficacy of cholestyramine to reduce vitamin D₃ levels in dogs has not been determined. The recommended dosage is 0.3–0.5 g/kg, dissolved in liquid and administered orally every 6–8 hr for 3–5 days, depending on the initial dose of cholecalciferol ingested. Premature initiation of calciuresis (see below) may disrupt normal calcium-phosphorus metabolism, triggering osteoclasts to move additional calcium into the blood stream, artificially increasing serum calcium and phosphorus levels and mimicking vitamin D₃ toxicosis.

Once the biochemical values begin to increase, there are two approaches to management. The first is to promote calciuresis by administering normal (0.9%) saline at 2–3 times normal rates. Furosemide at 2.5–4.5 mg/kg, PO, every 6–8 hr promotes calcium excretion but can also increase fluid loss (so hydration status should be monitored). Prednisolone at 1–3 mg/kg, PO, bid-tid, can reduce bone resorption as well as decrease calcium absorption from the intestine. Treatment with a phosphate binder (aluminum hydroxide 30–90 mg/kg, PO, in divided doses) to decrease phosphorus absorption and feeding a diet low in calcium should also be considered.

The preferred treatment for persistent significant hypercalcemia is pamidronate, an injectable bisphosphonate that inhibits osteoclastic bone resorption. It is administered at 1.3–2 mg/kg via slow IV infusion in saline over 2 hr. After administration, as the calcium and phosphorus levels start to decrease, supportive therapies (furosemide, prednisolone) should be tapered. A repeat dose may be required if significant hypercalcemia redevelops.

In the past, use of salmon calcitonin (administered at 4–6 IU/kg, SC, every 2–3

hr) has been suggested to decrease calcium and phosphorus levels, but this treatment is no longer used commonly. The two major disadvantages are that some animals may become refractory to calcitonin, and that once this therapy is instituted the use of pamidronate is not helpful.

Calcium and phosphorus levels should be monitored and treated until they return to baseline. Treatment may have to be continued for days or weeks because of the lipophilic nature of vitamin D₃. Renal function should be monitored, and other clinical signs treated as needed.

ZINC PHOSPHIDE

Zinc phosphide is a component in a number of mole, gopher, ground squirrel, and vole baits intended for outdoor use only. It is a dark gray powder, not soluble in water, and is commonly sold in 2%–5% bait pellets, paste, or tracking powder. In the past several years, an oat-based bait labeled for killing prairie voles has been marketed. There is evidently no way to identify this grain mixture, and bait ingestion has resulted in lethal exposure to a number of horses. The clinical effects of aluminum phosphide, used as a grain fumigator, are similar to those of zinc phosphide.

Lethal doses of zinc phosphide vary markedly between species and are much more toxic to species unable to vomit. The phosphide salts are unstable in an acid environment. At gastric pH, they degrade rapidly to form phosphine gas. Presence of food in the stomach, which will trigger release of gastric acid, increases the rate of this transition. Phosphine gas, when inhaled, results in acute noncardiogenic pulmonary edema. Vomiting, often hemorrhagic, is a common presenting sign in animals capable of vomiting. Tachypnea, ataxia, weakness, trembling, collapse, seizures, and death may ensue.

If there is no food in the stomach, undegraded zinc phosphide can be absorbed systemically. An animal surviving for 48 hr can then have liver and/or renal failure within 5–14 days due to absorption of intact zinc phosphide. Zinc phosphide is thought to block cytochrome C oxidase, leading to formation of highly reactive oxygen compounds, which cause most of the tissue injury; the most severe damage is in tissues with the highest oxygen demand, ie, brain, lungs, liver, and kidney.

Phosphine gas is a public health hazard. Animal owners and veterinary staff members must be cautious while inducing emesis, because they can be exposed to

phosphine gas from the presence of zinc phosphide bait in the stomach contents after vomiting. The gas is reported to have a garlic-like or fishy odor.

Management of zinc phosphide ingestion relies on effective decontamination. If the animal has not already vomited, emesis can be induced by use of apomorphine.

Decreasing gastric acid may be beneficial, via oral magnesium hydroxide antacid or using famotidine at 1 mg/kg, SC. IV fluid support is recommended while the animal is under observation. Use of activated charcoal may be considered; although metals are poorly bound by activated

charcoal, the larger zinc phosphide molecule may be. If vomiting is ongoing, administration of activated charcoal should be avoided because of the aspiration risk. Obtaining a baseline biochemical profile, with repeat evaluation of liver and renal values at 24, 48, and possibly 72 hr, is recommended. Use of *N*-acetylcysteine may be beneficial, with a loading dose of 140 mg/kg, followed by 70 mg/kg every 6 hr for six total doses. Administration of *S*-adenosyl methionine (SAM-e) may also be beneficial. Seizures should be controlled with diazepam or barbiturates, and other signs treated symptomatically.

STRYCHNINE POISONING

Strychnine is an indole alkaloid obtained from the seeds of the Indian tree *Strychnos nux-vomica*. Strychnine-containing baits are currently labelled for below-ground use and are intended for the control of pocket gophers. Their use as indoor pesticides has been eliminated since 1989. In the past, strychnine has been used as a pesticide to control rats, moles, gophers, and coyotes. Strychnine is highly toxic to most domestic animals. Its oral LD₅₀ in dogs, cattle, horses, and pigs is 0.5–1 mg/kg, and in cats is 2 mg/kg. Strychnine is considered a restricted-use pesticide. Its sale is forbidden in a number of states. Grain-laced or pelleted commercial baits (usually <0.5%) are often dyed red or green. Malicious or accidental strychnine poisoning, although not very common in the USA, occurs mainly in small animals, especially dogs and occasionally cats, and rarely in livestock. Most poisonings occur when nontarget species consume commercial baits. Young and large-breed, intact male dogs are more likely to be involved. Most poisonings are reported from the western USA.

Pathogenesis: Strychnine is ionized in an acidic pH and then rapidly and completely absorbed in the small intestine. It is metabolized in the liver by microsomal enzymes. The highest concentrations of strychnine are found in the blood, liver, and kidneys. Strychnine and its metabolites are excreted in the urine. Depending on the quantity ingested and treatment measures taken,

most of the toxic dose is eliminated within 24–48 hr.

Strychnine inhibits competitively and reversibly the inhibitory neurotransmitter glycine at postsynaptic neuronal sites in the spinal cord and medulla. This results in unchecked reflex stimulation of motor neurons affecting all the striated muscles. Because the extensor muscles are relatively more powerful than the flexor muscles, they predominate to produce generalized rigidity and tonic-clonic seizures. Death results from anoxia and exhaustion.

Clinical Findings: The onset of strychnine poisoning is fast. After oral exposure, clinical signs may appear within 30–60 min. Presence of food in the stomach can delay onset. Early signs, which may often be overlooked, consist of apprehension, nervousness, tenseness, and stiffness. Vomiting is possible but uncommon. Severe tetanic seizures may appear spontaneously or may be initiated by stimuli such as touch, sound, or a sudden bright light. An extreme and overpowering extensor rigidity causes the animal to assume a “sawhorse” stance. Hyperthermia (104°–106°F [40°–41°C]) due to stiffness and seizures is often present in dogs. The tetanic convulsions may last from a few seconds to ~1 min. Respiration may stop momentarily. Intermittent periods of relaxation are seen during convulsions but become less frequent as the clinical course progresses. The mucous membranes

become cyanotic and the pupils dilated. Frequency of the seizures increases, and death eventually occurs from exhaustion or asphyxiation during seizures. If untreated, the entire syndrome may last only 1–2 hr. There are no characteristic necropsy lesions. Sometimes, because of prolonged convulsions before death, agonal hemorrhages of heart and lungs and cyanotic congestion from anoxia may be seen. Animals dying from strychnine poisoning have rapid rigor mortis.

Diagnosis: Tentative diagnosis of strychnine poisoning is usually based on history of exposure and clinical signs. Recovery of strychnine alkaloid from the stomach contents, vomitus, liver, kidneys, or urine should be considered diagnostic. Sometimes, urine may not have a detectable amount of strychnine present if analyzed 1–2 days after exposure; therefore, multiple samples should be collected and analyzed. Occasionally, poisoned animals may show presence of undigested grain-laced red or green strychnine bait in the stomach.

Strychnine poisoning can be confused with poisonings by several other seizurigenic substances such as metaldehyde; tremorgenic mycotoxins (penitrem a); organochlorine, organophosphate, or carbamate insecticides; fluoroacetate (1080); zinc phosphide; nicotine; 4-aminopyridine; caffeine; or human medications (tricyclic antidepressants, 5-fluorouracil, metronidazole, isoniazid). Acute, massive hepatic necrosis (hepatic encephalopathy) can also produce clinical signs that resemble those of strychnine poisoning.

Treatment: Strychnine poisoning is an emergency, and treatment should be instituted quickly. Treatment should be aimed at decontamination, control of seizures, prevention of asphyxiation, and supportive care. Seizures should be controlled, and symptomatic animals stabilized before decontamination is attempted.

Decontamination consists of removal of gastric contents by inducing emesis or gastric lavage, and binding of remaining

bait in the GI tract with activated charcoal. Because of the rapid onset of clinical signs, emesis may be of limited value in most cases. If exposure is recent and no clinical signs are present, emesis should be induced with 3% hydrogen peroxide (small animals and pigs) at 1–2 mL/kg, PO, maximum 3 tbsp, repeated once after 30 min if vomiting has not occurred; apomorphine (dogs only) at 0.03 mg/kg, IV, or 0.04 mg/kg, IM; or xylazine (dogs or cats) at 0.5–1 mg/kg, IV or IM. If emesis cannot be induced, gastric lavage should be performed with tepid water. Animals already seizing should be anesthetized first (with pentobarbital), and an endotracheal tube passed before gastric lavage. After emesis or gastric lavage, activated charcoal should be administered at 2–3 g/kg in small animals and 0.5–1 g/kg in large animals with a cathartic such as magnesium sulfate at 250 mg/kg, PO, or sorbitol at 1–3 mL/kg, PO.

Seizures should be controlled in small animals with pentobarbital, IV to effect, repeated as necessary. Muscle relaxants such as methocarbamol at 100–200 mg/kg, IV, also work well; they should be repeated as needed with a maximal dose of 330 mg/kg/day. In large animals, chloral hydrate or xylazine can be used to control seizures. Other medications such as glyceryl guaiacolate (5%, 110 mg/kg), diazepam, and xylazine have been used in dogs to control seizures with variable success. Propofol (3–6 mg/kg, IV, or 0.1–0.6 mg/kg/min as a constant-rate IV infusion) can also be tried to control seizures in dogs or cats. Isoflurane inhalation anesthesia can be used in small animals if preceding measures to control seizures do not work.

Severely affected dogs should be intubated, and artificial respiration provided. Acidification of urine with ammonium chloride (100 mg/kg, bid, PO) may be useful for ion trapping and urinary excretion of the alkaloid. IV fluids should be administered to force diuresis and maintain normal kidney function. Hyperthermia treatment (fans, cool bath) should be given if necessary. Acid-base balance should be monitored and corrected as needed. Most clinical cases may require 1–3 days of treatment.

TABLE 2 WEIGHTS AND MEASURES EQUIVALENTS AND CONVERSIONS

Length	1 m = 39.37 in.	1 ft = 30.48 cm
	1 yd = 91.44 cm	1 in. = 2.54 cm
Weight^a	1 kg = 2.205 lb	1 lb = 0.454 kg
	1 g = 0.035 oz	1 oz = 28.35 g
	1 mg = 0.015 grain	1 grain = 64.8 mg
	1 ton = 2,000 lb	1 metric ton = 1,000 kg = 2,205 lb
Capacity		<i>Imperial system:</i>
	1 gal. = 3.785 L	1 gal. = 4.55 L
	1 quart = 0.946 L	1 quart = 1.136 L
	1 pint = 473.2 mL	1 pint = 568.26 mL
	1 oz = 29.57 mL	
	1 tablespoon = 15 mL	
	1 teaspoon = 5 mL	

^a Avoirdupois (used in the USA as the common system of measuring weight) unless otherwise specified

TABLE 3 PERCENTAGE, PPM, AND PPB CONVERSIONS

ppm	ppb	Percentage
0.001	1	0.0000001
0.01	10	0.000001
0.1	100	0.00001
1	1,000	0.0001
10		0.001
100		0.01
1,000		0.1
10,000		1

Other useful conversions: 1 mg/kg = 1 ppm; 1 g/ton = 1.1 ppm; 100 g/ton = 110 ppm

TABLE 14

MILLIGRAM-MILLIEQUIVALENT CONVERSIONS AND ATOMIC WEIGHTS

Ion	Atomic Weight	Valence
Hydrogen (H)	1	1
Carbon (C)	12	4
Nitrogen (N)	14	3
Oxygen (O)	16	2
Sodium (Na)	23	1
Magnesium (Mg)	24	2
Phosphate (P) ^a	31	3, 5
Chlorine (Cl)	35.5	1
Potassium (K)	39	1
Calcium (Ca)	40	2

Note: The milliequivalent (mEq) is the unit of measure often used for electrolytes. It indicates the chemical activity, or combining power, of an element relative to the activity of 1 mg of hydrogen. Thus, 1 mEq is represented by 1 mg of hydrogen (1 mole) or 23 mg of Na⁺, 39 mg of K⁺, etc.

$$\text{mEq/L} = \frac{(\text{mg/L}) \times \text{valence}}{\text{molecular weight}}$$

$$\text{mg/L} = \frac{(\text{mEq/L}) \times \text{molecular weight}}{\text{valence}}$$

^a As phosphorus, inorganic
